Ease of reduction is variable and depends mainly on the degree of eburnation of the fracture surfaces. Smooth, eburnated fracture margins make reduction difficult. If the femoral shaft is held with forceps, leverage is provided when attempting reduction. However, reduction is maintained digitally because clamps cannot be applied. Predrilling the glide hole across the femoral shaft also minimizes the length of time that the fracture must be digitally maintained in reduction.

It is difficult to accurately estimate the ideal length of screw from preoperative radiographs; thus, intraoperative palpation and measurements are essential. To assess the depth and direction of drilling, a pin or drill bit of the same length is placed on the exterior of the bone in a parallel position as drilling is performed. This provides additional visual and tactile help for alignment as holes are drilled into the head of the femur. If at all possible, two screws should be used to ensure rotational stability.

CHAPTER 102

Femur and Pelvis

Dean W. Richardson

Closure of the wound should be in layers with synthetic absorbable suture. Pre-placing several sutures in the joint capsule before tying is recommended. If a trochanteric osteotomy was performed, it must be repaired with a tension-band technique. Either two screws or two smooth pins can be used to replace the trochanter, but both must be supported distally with 1.25- or 1.5-mm-diameter wire. The wire is passed through a drill hole across the femoral shaft made 5 to 7 mm distal to the osteotomy. In larger foals, two wires are usually used. If screws are used to replace the trochanter, it might help to feed the screws through washers so that the tension-band wire comes to lie between the washer and the bone, which secures the fixation.

Other types of proximal femur fractures involve the greater trochanter or, more commonly, the third trochanter. These fractures can be diagnosed with physical examination or scintigraphy. Ultrasonography can then be used to more specifically define the injury without general anesthesia. Unless fractures are associated with a wound or become sequestrated, they should be treated conservatively with stall rest for several months.

Mid-diaphyseal Fractures
Mid-diaphyseal fractures are the most common type and are the fractures most amenable to surgical repair. Most have a spiral or long oblique shape or are comminuted.

The skin incision is made laterally over the length of the bone between the greater trochanter and the lateral condyle. After the fascia lata is incised, it is easy to separate the vastus lateralis and biceps femoris and identify the fracture hematoma. When the fracture hematoma is identified, the separation of the musculature is easier to define from the inside of the hematoma. The attachments to the third trochanter may need to be severed to provide exposure at the proximal end of the bone.

Comminuted fragments should be independently reduced with screws inserted in positions outside of the planned locations of the plates until the fracture is reconstructed into two main pieces. Comminution in some cases is severe and requires extensive reconstruction. It is useful to place 3.5-mm cortex screws in lag fashion to reduce small fragments, countersinking their relatively small heads deep enough that the plates can be placed over them (Fig. 102-1).
If there is a barrel stave configuration to the fracture extending down the diaphysis, cerclage wires or cables can be used to prevent splitting the bone.

When the fracture is reconstructed to two pieces, reduction is usually possible by simply elevating the fragment ends out of the incision, aligning them properly, and folding the bone ends back into position. For long oblique fractures, it might be necessary to clamp the bone in an overriding position before sliding it incrementally by direct traction into reduction. Nylon cable ties or heavy cerclage wires can be pre-placed to help hold the reduction as it progresses. Vigorous traction might be necessary; therefore, it is essential that the foal’s tail and body be tied securely with ropes and girths to the surgery table.

After reduction is obtained, bone clamps are applied. If possible, one or two screws are placed with lag technique across the oblique fracture in locations where they will not interfere with the lateral plate. The bone reduction forceps are removed, allowing application of a long, 5.5-mm limited-contact dynamic compression plate (LC-DCP), broad dynamic compression plate (DCP), or locking compression plate (LCP) with 5.5-mm cortex screws laterally. Alternatively, the plate can be placed with a bone clamp maintaining the reduction, but this is more difficult to achieve.

After applying the lateral plate, a shorter (usually also broad) LC-DCP, DCP, or LCP is placed cranially. Hohmann retractors provide adequate exposure to position the plates and insert the screws (see Fig. 102-1, C to E). Considerable effort at retraction is sometimes necessary to obtain exposure of the cranial plate for drilling and screw insertion. If necessary, it is possible to make stab incisions through the quadriceps muscle to drill, tap, and insert screws into the cranial plate. Lag technique is applied in plate screws crossing any fracture plane for additional compression and stability. Interfragmentary compression greatly increases the overall stability of the repair. The two plates must be staggered a half-hole apart, and the screws must be inserted perpendicular to the long axis of the plates to prevent interference of screws. The lateral plate should be luted. All cortex defects are filled with autologous cancellous bone.

The incision is closed in at least three layers: the fascial margins of the vastus lateralis and the biceps femoris, subcutaneous tissues, and skin. Interrupted sutures are recommended because wound problems are common and local drainage is sometimes necessary. Because of the considerable muscle trauma and compression, bandaging is impossible; closed suction drainage is essential to minimize accumulation of serum.

Although there is limited clinical experience to date with LCPs (see Chapter 81), they offer significant advantages in terms of stability, mainly because the locking screws prevent movement of the cortex screw heads within the combi hole7 (Fig. 102-2).

An alternative technique for simple diaphyseal fractures of the femur is insertion of an interlocking intramedullary nail8 (see Fig. 81-34). The axial position of the nail affords excellent bending stability, and the transfixing screws provide rotational stability. If possible, supplemental fixation in the form of lag screws, cerclage wires, or a plate with unicortical screws can be used in oblique or spiral fractures.
Regardless of the plate selected, 5.5-mm cortex or 6.5-mm cancellous screws should be used. The para-patellar incision is closed with large tension-holding sutures (cruciate, overlap, or mattress), and a meticulously managed suction drain is used in the subcutaneous tissues.

**Prognosis**

The prognosis for fractures of the femur is guarded because of the high risk of complications. As a result of muscle trauma and because a pressure bandage cannot be used on the area, surgical incisions are susceptible to extensive serum accumulations. Wound dehiscence and sepsis are common problems. If complications are avoided, however, healing of fractures of the femur is remarkably rapid in young animals because of excellent vascularity and muscle coverage. Callus is radiographically visible in foals within a few weeks.

Failure of plates and screws is rare, except when there is a bone defect in the caudal cortex. Such a defect leads to excessive cyclic loading of the implants and fatigue failure. If fracture healing is uncomplicated, it is not advisable to remove the implants because of the potential for healing problems. In distal physeal fractures, the plate might have to be removed if it is interfering with joint function or if there is significant remaining growth potential. Unfortunately, many physeal fractures of the distal femur result in

**Distal Femoral Fractures**

Distal femoral fractures are most commonly encountered in older weanlings and yearlings and are usually Salter-Harris type II, with the metaphyseal fragment positioned caudally. Salter-Harris types III and IV fractures have also been reported but are less common. Any distal femoral fracture can be initially misdiagnosed as a stifle lesion because of the location of the swelling (Fig. 102-3). Fractures of the distal femur tend to be quite unstable and therefore require surgical repair.

The fracture is approached through a craniolateral incision between the vastus lateralis and biceps femoris muscles. The incision is extended distally to the level of the tibial crest. The lateral femoropatellar ligament must be transected to allow a parapatellar arthrotomy and patellar luxation. Reduction may be quite difficult to achieve. Like many physeal fractures, exact anatomic alignment is difficult to assess. The metaphyseal part of the fracture is not readily visible and is covered by the extensive soft tissues on the distal caudal femur.

After reduction is achieved, a long screw can be placed through the exposed intercondylar notch and into the metaphyseal fragment positioned caudally while the lateral plate is applied. Because the epiphyseal fragment is small, a specialized plate is usually preferred. The strongest plate, which is best suited for larger yearlings, is a dynamic condylar screw (DCS) plate. The DCS plate is difficult to contour because of its large cross section.

Special care must be taken to fit the plate accurately on the horse’s curved distal femur, because the plate was designed for the straight human femur. However, this plate provides superior stability in the distal fragment (Fig. 102-4). In horses weighing less than 175 kg, the condylar buttress plate with a flared end accommodating several screws is easier to apply and is strong enough despite its smaller cross section. A cobra head plate may be used, although it is difficult to conform to the bone. The broad LCPs with 5.0-mm locking screws also have potential for use in this location (see Fig. 102-2).
permanent closure of the growth plate and consequently a shortened femur. This is acceptable for breeding soundness, because the animal can compensate somewhat by increasing its joint angles in the stifle and hock.

Although some fractures of the femur have been successfully managed conservatively, younger animals often rapidly develop a serious varus deformity in the contralateral limb (Fig. 102-5). Because these fractures can be repaired successfully in foals, the conservative approach should be reserved for older animals in which the surgical approach is too daunting or for cases where comminution is severe enough that reconstruction is not feasible.

**FRACTURES OF THE PELVIS**

Fractures of the pelvis occur in all animals of all ages but are disproportionately common in foals and yearlings. Most follow a distinct traumatic event, such as a fall. In adult

---

**Figure 102-4.** A, Salter-Harris type II fracture of the distal femur. B and C, The fracture was repaired with a dynamic compression screw (DCS) plate applied laterally and augmented with a five-hole narrow dynamic compression plate (DCP) containing long screws penetrating the medial condyle. One single screw was buried in the articular surface to provide additional stability to the cranial aspect of the reconstruction. Longitudinally placed screws should augment the plate fixation. (Courtesy C. Lischer, University of Zurich.)
horses, pelvic fractures can occur during intense exercise without obvious trauma.

The most obvious clinical sign is overt lameness either of the swinging or supporting limb type. External swelling or asymmetry of palpable pelvic landmarks (e.g., the tuber coxae, tuber ischii, tuber sacrale, and greater trochanters) can be present. It is helpful to measure the distances between these landmarks and to compare the two sides. Pain can be elicited by manipulation of the limb or by direct pressure over the trochanter or other prominences. Examination per rectum can reveal obvious asymmetry, especially with acetabular fractures in which there is often a rounded, firm swelling over the fractured region.

Crepitus can be difficult to appreciate externally in horses with pelvic fractures, but it is often more obvious if the horse’s weight is shifted or if the horse is walked a few steps during a rectal examination. Vigorous manipulation of the limb by an assistant can also be helpful in some cases, although care should be taken to test the horse’s pain response to such manipulation before the rectal examination is undertaken. Crepitis is usually appreciated more easily in the first day or two after the injury.

In chronic cases, pelvic musculature is usually atrophied, although this is obviously not specific for a pelvic injury. The medial thigh region should always be checked for asymmetry, because dependent swelling often develops in this area, especially with displaced acetabular and ileal fractures. The most dramatic presenting signs are seen with a laceration of a major artery (usually the internal iliac artery). This results in bleeding into the abdomen or thigh that is severe enough to cause shock or death.14,15

A definitive diagnosis of pelvic fractures is made with radiographs. This usually requires general anesthesia, although a technique for standing pelvic radiography has been described.16 Even under general anesthesia, there are significant limitations in the sensitivity of radiographs of the pelvis in adult horses. Consequently, nuclear scintigraphy, either with an imaging or point-counting technique, is often used for screening.17-19 Scintigraphy is the only technique that can identify subtle injuries such as ileal stress fractures. If a displaced fracture is suspected, a simpler and less expensive alternative is ultrasonography; it is possible to clearly identify discontinuities of a cortical surface in accessible locations.20,21 Ultrasonography is particularly useful for diagnosing tuber coxae fractures.

Treatment

Treatment of pelvic fractures is almost always conservative, although displaced iliac shaft fractures in foals can be repaired successfully with internal fixation (Fig. 102-6). The ilium is approached by elevating the gluteal musculature sharply along its ventral attachments and forcefully retracting the musculature dorsally with Hohmann elevators. The fragments are reduced and secured with bone plates. In non-articular fractures, anatomic reduction is not mandatory for a good result. Surgical repair of pelvic fractures in foals is restricted to those with marked displacement and a need for athletic function.

There are no reported cases of the successful repair of acetabular fractures in horses of any age, although it is feasible to approach the dorsal rim in younger foals or miniature horses. Displaced tuber coxae fractures (knocked-down hips) are usually not treated surgically either, although removal should be considered if they are open and draining.

In adult horses, stall rest for at least 3 to 4 months is combined with adequate analgesia, support bandaging, and frog support on the contralateral limb. Epidural analgesia can be used with caution, especially to manage the more intense pain in the initial period after the injury. Younger horses heal more quickly but also develop limb deformities more readily in the contralateral limb (see Fig. 102-5).

Prognosis

The prognosis for pelvic fractures depends primarily on the degree of displacement. Nondisplaced fractures of any portion of the pelvis, even those involving the acetabulum, heal without serious consequences, whereas displaced injuries that cause persistent pain lead to muscle wasting, contralateral limb and foot problems, and coxofemoral arthritis. In mares, markedly displaced fractures can

Figure 102-5. A 6-month old weanling suffering from a femoral shaft fracture of 1 month’s duration in the right hindlimb, which was treated conservatively. Note the marked varus deformity in the left hindlimb.
compromise the birth canal and lead to dystocia. In one study, a successful outcome occurred in 77% of horses that were not euthanized immediately after the pelvic fracture was diagnosed. Because surprisingly rapid improvement and healing can occur, precipitous decisions to euthanize horses with pelvic fractures should be avoided, unless it is absolutely clear that recovery is impossible or the economic pressures dictate against continued treatment.

COXOFEMORAL LUXATIONS

Coxofemoral luxations are rare in equids but are more common in ponies and miniature horses than in larger animals. Most occur after falls, after attacks by larger horses, or while the animal is struggling to extract an entrapped limb or straighten an upwardly fixed patella. Coxofemoral luxations and femoral head fractures can occur in horses and foals wearing full hindlimb casts.

Clinical diagnosis of coxofemoral luxation is not difficult except to distinguish it from a femoral head fracture, which can be achieved through radiography or ultrasonography. The affected horse is very lame and holds the distal limb externally rotated. Because most luxations occur craniodorsally, the point of the tarsus is higher than the normal side when the horse is viewed from behind. Manipulation of the limb might or might not yield a soft, clicking crepitus.

**Treatment**

Treatment of coxofemoral luxation in miniature horses and ponies has been accomplished by reduction and primary repair or by excision arthroplasty.

Surgical repair involves a craniodorsal approach to the hip with or without greater trochanteric osteotomy. If a trochanteric ostectomy is elected, it is advisable to pre-drill one or two holes to facilitate tension-band repair during closure. Before the femoral head is reduced, the joint is cleaned of fibrin and any debris. Reduction often requires mechanical assistance either with a calf jack or a pulley system rigged up in the operating room. A hip skid, which is a long lever with a curved spoon-like end, can be helpful in reducing the luxation. In most cases, replacement alone is not successful because of continued instability. Therefore, toggle pinning or augmentation of the lateral joint capsule with synthetic sutures attached to screws might be necessary. The latter technique involves placing screws above the cranial acetabular margin and lateral femoral shaft just distal to the neck. A large braided suture is tied around the screw heads to help prevent the head from moving proximolaterally. Washers can help to minimize slippage of the suture material from under the screw heads.

Femoral head and neck excision is unlikely to be successful, except in small ponies and miniature horses. The surgical exposure is achieved through a craniolateral approach, and an oscillating saw, Gigli wire, or wide osteotome is used to transect the femoral neck as close to the shaft as possible. Postoperatively, the horse should be kept on optimal footing to prevent the animal from slipping. Use of soft rope hobbles may be helpful to prevent abduction if the horse can tolerate them.

**FRACTURES OF THE INCISORS, MANDIBLE, AND PREMAXILLA**

Trauma to the head often results in fractures of the teeth, incisive bone, mandible, premaxilla, or maxilla. These injuries occur as blunt trauma from kicks, falls, and collisions or from being startled in the stall while cribbing on stall slats or mesh wire. Sudden jerking of the head while chewing on stationary objects results in avulsion fractures of the incisors. Whatever the cause, these fractures can be repaired with good cosmetic and functional results. Several factors make this possible. There is good soft tissue covering with an abundant vascular supply. Because the bones of the head are not subjected to the same loading forces as the bones of the extremities, the requisites for fracture fixation are less demanding. The teeth serve as welcome stabilizing aids. Implants of adequate strength are available, and the instrumentation required is in most cases inexpensive and readily available.

**Diagnosis**

A thorough physical examination is the basis for a correct diagnosis. One of the first signs of a fracture of the jaws is excessive drooling and lack of appetite. Soft tissue swelling, hemorrhage, instability, and malalignment of the teeth and bones are usually noticed on closer inspection. A fetid odor is usually present with open fractures that are several days old. Malocclusion of the incisors can be induced manually even in normal horses because of the normal side-to-side mobility of the temporomandibular joint. However, both mandibles will move in the same direction with manipulation unless a fracture is present, in which case, one side of the mandible can be manipulated independently of the other. Often, soft tissue swelling obscures the detection of a malalignment, especially if the fracture is located under the masseter muscles. Horses might object to manipulation and examination of the oral cavity because of pain. A protruding tongue should alert the clinician to suspect a bilateral fracture. Drooling occurs as a result of an inability to close the mouth.

The diagnosis is in most cases not difficult, but other structures might be injured concurrently; therefore, the nasal passages and cranial nerves should be examined. Horses can become significantly dehydrated after hemorrhage and salivary loss, which can be compounded by the patient’s reluctance to drink. This is especially true if the fractures are not detected in a timely manner. The physical examination also should include cardiovascular parameters that would identify potential anesthetic risks. In by far the majority of the cases, repair is not an emergency procedure, allowing adequate time to arrive at a comprehensive surgical plan.

FRACTURES OF THE INCISORS, MANDIBLE, AND PREMAXILLA

Trauma to the head often results in fractures of the teeth, incisive bone, mandible, premaxilla, or maxilla. These injuries occur as blunt trauma from kicks, falls, and collisions or from being startled in the stall while cribbing on stall slats or mesh wire. Sudden jerking of the head while chewing on stationary objects results in avulsion fractures of the incisors.

Whatever the cause, these fractures can be repaired with good cosmetic and functional results. Several factors make this possible. There is good soft tissue covering with an abundant vascular supply. Because the bones of the head are not subjected to the same loading forces as the bones of the extremities, the requisites for fracture fixation are less demanding. The teeth serve as welcome stabilizing aids. Implants of adequate strength are available, and the instrumentation required is in most cases inexpensive and readily available.

Diagnosis

A thorough physical examination is the basis for a correct diagnosis. One of the first signs of a fracture of the jaws is excessive drooling and lack of appetite. Soft tissue swelling, hemorrhage, instability, and malalignment of the teeth and bones are usually noticed on closer inspection. A fetid odor is usually present with open fractures that are several days old.

Malocclusion of the incisors can be induced manually even in normal horses because of the normal side-to-side mobility of the temporomandibular joint. However, both mandibles will move in the same direction with manipulation unless a fracture is present, in which case, one side of the mandible can be manipulated independently of the other. Often, soft tissue swelling obscures the detection of a malalignment, especially if the fracture is located under the maseter muscles. Horses might object to manipulation and examination of the oral cavity because of pain. A protruding tongue should alert the clinician to suspect a bilateral fracture. Drooling occurs as a result of an inability to close the mouth.

The diagnosis is in most cases not difficult, but other structures might be injured concurrently; therefore, the nasal passages and cranial nerves should be examined. Horses can become significantly dehydrated after hemorrhage and salivary loss, which can be compounded by the patient’s reluctance to drink. This is especially true if the fractures are not detected in a timely manner. The physical examination also should include cardiovascular parameters that would identify potential anesthetic risks. In by far the majority of the cases, repair is not an emergency procedure, allowing adequate time to arrive at a comprehensive surgical plan.
In most cases, radiographs are difficult to interpret because of the complexity of the bones in the head and the presence of the teeth, which often are superimposed over fracture lines. Nevertheless, radiographs often demonstrate fractures even with minor malalignment and instability. Also, radiographs provide information about the precise location of the tooth roots in relation to the fracture, which helps in devising a surgery plan that avoids damage to the permanent teeth. Radiographs often aid in detecting potential sequestrum formation. Computed tomography greatly improves preoperative appreciation of the fracture configuration, especially when three-dimensional reconstruction of the fractured bone is obtained (Fig. 103-1).

Not all fractures require repair. Unilateral fractures of the mandible, maxilla, premaxilla, or incisive bone that are minimally displaced and do not result in significant malocclusion may be treated conservatively. Indications for repair include fractures that are unstable, result in malocclusion of the teeth, or are bilateral. Other considerations that might favor surgical repair include improved cosmesis because of decreased callus formation, more rapid healing in the face of increased stability, and horses that are either unable or reluctant to eat because of pain.

Preoperative Management
Simple dental fractures that do not require fixation devices that extend caudal to the canine teeth can be managed in the standing, sedated horse with regional anesthesia. Local anesthesia is easily accomplished by infiltrating 5 mL of lidocaine or mepivacaine around either the mental or infraorbital nerves at their exit point from their respective foramina. Bilateral infiltration of the nerves is required in most cases.

The standing position facilitates observation of symmetry during surgical repair. However, general anesthesia is preferred because of the potential for injury to the surgeon by the patient in response to painful stimuli. Intravenous anesthetic regimens (see Chapter 20) are appropriate in most of the simple fractures, because patient and surgeon preparation and positioning requirements are minimal, so that repair may begin immediately after induction. To allow
unimpeded access to the fracture, nasotracheal intubation is preferred in most cases where inhalation anesthesia is desired or indicated.

The location of the fracture, its complexity, and the personal preferences of the surgeon dictate patient positioning on the surgery table. Most uncomplicated unilateral fractures are repaired in lateral recumbency. Access to both sides of the mouth is required for bilateral fractures and is most easily accomplished with the horse in dorsal recumbency, with the poll flexed so that the surgeon can look down into the horse's mouth.

Preoperative planning should include the likelihood of fracture reduction and which implants will provide the best stability. All necessary equipment must be ready and sterilized. Additionally, any splint that might be required must be pre-shaped, ideally on a cadaveric specimen of approximately the same size to reduce anesthesia time.

Before repair, the mouth is rinsed with water to remove feed material; a dental pick is used to remove any feed material from fracture lines. The oral cavity is contaminated, and surgical scrubs are of dubious value if intraoral wiring alone is to be used. Repair methods that use internal fixation devices deserve all of the precautions and considerations that internal fixation in other areas require because the implants are usually left in place. Prophylaxis against tetanus is indicated in all cases. Perioperative broad-spectrum antibiotics are strongly encouraged, because the surgery is usually performed in a contaminated field.

Surgical Considerations
The tension side of the jaw is the oral surface of both the mandible and maxilla, and surgical repair should be directed accordingly when possible. Unilateral fractures of the mandible are partially supported by the intact contralateral side. This aids in the stability of the final repair. Avulsion fractures of the incisors, mandible, and premaxilla are usually simple fractures. The ends of the fractured bone usually interdigitate well and can be repaired using intraoral wiring.

Fractures of the incisors that result from kicks or collisions push the teeth caudally. These fractures are usually associated with a considerable amount of instability and some comminution of the bone caudal to the incisors. The extent of comminution can be assessed during physical examination by the stability of the fracture once it is reduced and by the resistance to collapse with manual manipulation.

Intraoral wiring alone tends to collapse comminuted fractures and results in malocclusion when the wires are tightened. In these cases, it is necessary to provide a buttress to maintain length and prevent collapse. This can be accomplished by intraoral splinting, external fixators, or bone plates applied in buttress fashion.

Closed reduction is desirable to preserve blood supply and to leave soft tissues intact for support. Every effort should be made to prevent contamination of healthy tissues by exposure to the oral cavity. Because accuracy of reduction is in most cases readily determined by visual inspection of the teeth, open reduction is often not necessary to ensure alignment of the fractures. The soft tissue attachments of the gingiva should not be disrupted. Small bone fragments devoid of their soft tissue attachments should be removed when the fracture is open. However, any bone fragment attached to the gingiva or periosteum should be left in place.

Loose teeth should never be removed until the fracture has healed and clear evidence is present that they are devitalized. Viability is not always easy to determine at the time of surgery, and many teeth will survive even if they are loose at the time of repair. More importantly, the teeth often serve a vital function as anchor sites in the thin flat bones of the jaws and quite often support the neighboring teeth when wires are used in the repair.

Intraoral wiring and external fixation methods have some advantages over internal fixation using plates and screws in fractures of the mandible and maxilla for several reasons. Intraoral wiring configurations are inexpensive and almost infinitely variable and adaptable to almost any fracture configuration. Bone in this area is soft, and screws can be easily stripped. The roots of both permanent and deciduous teeth occupy a large part of the mandible and maxilla and make placement of screws for plate fixation difficult without damaging the teeth. Radiographic control is usually necessary if internal fixation methods are used. Accuracy of screw placement, screw length, and proper bone engagement of the screws are not easily determined without intraoperative radiographs.

The oral cavity contains a large population of resident microflora. Fractures are usually open and contaminated so that internal fixation often results in infection, thus necessitating eventual removal of the implant. Instrumentation for internal fixation requires more expertise, and the procedures are more time consuming. It is difficult to place bone plates on the tension surface. This does not preclude their use, and bone plates can result in satisfactory repair when placed on the lateral aspects of the mandible or maxilla because in this location the plates are loaded parallel to their width and not their thickness, which provides greater resistance against cyclic loading.

When repairing fractures of the teeth, mandible, and premaxilla, the goals are anatomic alignment and stable fixation to restore the ability to masticate. Involved incisors are best ground down to prevent contact with the opposing tooth arcade during mastication, which can cause decreased disturbance of fracture healing. Many successful methods have been reported, and the simplest method of repair that achieves these goals should be applied to any situation. Techniques are often combined as necessary.

Surgical Techniques

**Intraoral Wires**

**WIRING OF THE INCISORS**
Fractures involving the incisors, incisive bone, symphysis of the mandible, and premaxilla are amenable to intraoral wiring. The wound is properly cleaned and the potential damage to tooth roots or deciduous tooth buds is assessed. Fracture reduction is accomplished by manual manipulation.

A 14-gauge needle is inserted between the teeth at the gum line, and a 1.25-mm diameter stainless steel wire is threaded through the needle (Fig. 103-2, A). Care is taken to prevent sharp bends in the wire from developing while winding it around the teeth, because these bends prevent effective tightening of the wire. Additionally, cyclic loading of the wire during eating will straighten the wire and in
doing so loosen the fixation. Sharp bends also predispose the wire to failure because of local weakening through prestressing. The wires are kept tight during application, and any slack in the wire is removed after each tooth is encircled. Fractured teeth are united to adjacent healthy ones with a figure-eight wire passed around all selected teeth and tightened at one end (Fig. 103-2, B). Another technique involves multiple overlapping cerclage wires placed around the selected teeth. Each wire fastens the unstable teeth and associated bone to the normal teeth until alignment and stability are achieved. The selection of the technique to be applied is at the discretion of the surgeon.

Wire fixation is most easily accomplished by simple interrupted wires encircling the teeth. One or two wires are usually sufficient to stabilize most simple fractures of the incisors. After each wire is tightened, the fracture is manipulated to ascertain the alignment and stability. Wire repair applying the figure-eight technique unites all teeth in one fixation, but because of the relatively long wire arranged in several circles around the involved teeth, tightening the wire is more difficult. Repair is adequate if the incisors cannot be displaced by manual pressure.

A standard wiring technique applied in humans has been proposed. Wire loops are inserted between each tooth from the oral to the labial side (Fig. 103-2, C). One end of the wire is fed through each loop and is tightened with the other end. Each wire loop is subsequently tightened, resulting in a constricting wire loop around each tooth and therefore increased stability. This technique provides a rigid fixation that allows the patient to eat for months while the fracture heals (Fig. 103-3).

Fractures that involve the corner incisors need some sort of anchoring farther caudally. In male horses the canine tooth may serve as such an anchor (Fig. 103-4). It is usually necessary to make a notch in the canine tooth at the gum line with a small triangular file to prevent the wire from slipping off of the tooth. An alternate approach to a caudal anchor is to insert a 4.5-mm cortex screw into the interdental space and wrap the wire around the screw head. Another technique is to drill a 2.5-mm hole across the lateral edge of the interdental space and feed the wire through it (see later). Tension band wiring can also be achieved by feeding the wire around the second premolar and tightening the wire.

In rare cases, cerclage wires may be applied in a circular manner around oblique unilateral fractures of the interdental space (Fig. 103-5). The intact opposite side of the mandible ensures maintenance of mandible length and some stability of the fracture ends, and the cerclage wires maintain the fragment ends in approximation and provide some compression across the fracture.

Hemicerclage wires are very useful in fractures of the mandible. Initially a K-wire of 2 to 2.5 mm is introduced across the fracture. The two ends of the pin are united across the surface of the bone in figure-eight fashion and solidly tightened, providing axial compression across the fracture (Fig. 103-6). This technique is also very effective in fractures of the symphysis of the mandible in very young foals, where the bone has inadequate strength for lag screw fixation (see later).

Interdental wiring becomes progressively more difficult as fractures occur more caudally on the mandible. It is very
difficult to wire one cheek tooth to another one with the limited room to work in via an oral approach.

An alternative method of figure-eight wiring that does not use bone screws can be performed by anchoring the wire in the bone through holes drilled through the mandible on each side of the fracture (Fig. 103-7). The surgical approach is the same. A 2-mm drill bit is used to make a hole from a lateral to a medial direction through the mandible near the ventral border approximately 2 cm from the fracture. Figure-eight wiring is performed using the drill hole as an anchor site. This technique is adequate for young foals but not for adult horses with fractures of the interdental space.

**TENSION-BAND WIRING TO THE CHEEK TEETH**

Fractures of the diastema of the mandible are good candidates for repair with intraoral wiring. Unilateral fractures can be realigned and stabilized with a wire placed around the second premolar and secured to the incisors.

Figure 103-3. Intraoral wiring of a mandible fracture in an 11-year-old Arabian stallion. A, Preoperative intraoral radiograph of a fracture involving the base of the incisor teeth. B, The technique shown in Fig. 103-2, C was applied. Note the worn-down incisor teeth because of continuous cribbiting. C, Postoperative intraoral radiograph of the fixation. Because the corner incisors were involved in the fracture as well, tension-band wiring was used. D, Four-month follow up intraoral radiograph after curetting of an abscess near the tooth roots. E, Seven-month follow-up at the time of wire removal. The fracture has healed and the infection has resolved.

Figure 103-4. Tension-band wiring of incisors to the canine teeth used to repair a fracture involving the incisors. Note that an indentation (arrow) was created into the nuchal aspect of the canine teeth with a rasp to anchor the wire.
Under general anesthesia, the horse is placed in lateral recumbency on the surgery table with the fractured side toward the surgeon. With the help of hypodermic needles, the interdental space at the gingival level between 306 and 307 or 406 and 407 (see Chapter 30) is identified. Occasionally, the interdental space farther back is also used. Digital palpation facilitates identification as well.

Once the space is identified, a stab incision is made through the cheek. A 2.5-mm-diameter drill sleeve is introduced through the stab incision and placed over the interdental space, and a 2.5-mm hole is created between the teeth at the level of the gingiva (Fig. 103-8). A 1.25-mm diameter stainless steel wire is threaded through the cheek and the hole that was drilled between the teeth. Both ends of the wire are pulled into the mouth and drawn rostrally out of the mouth. The wire is crossed and looped around the intermediate and corner incisors by threading the wire between the teeth through a 14-gauge needle. The wire is twisted in the interdental space (Fig. 103-9). This results in a satisfactory repair because the wires compress the fractured

Figure 103-5. A, Preoperative radiograph of a long oblique fracture through the interdental space in a Shetland pony. D, Radiograph after implant removal.

Figure 103-6. Hemicerclage fixation of a symphysis fracture. Two pins are placed across the symphysis. Figure-eight wires are placed around the protruding ends and solidly tightened to effectively stabilize the fracture. This type of fixation may also be applied to other locations.

Figure 103-7. Figure-eight wiring of a vertical fracture of the mandible through the interdental space. The holes are created with a 2.5-mm drill bit or a Steinmann pin.
bone ends, resulting in stability. Additional stability is provided by the contralateral intact hemi-mandible. Tension band wiring to the premolars may be performed bilaterally, if indicated.

Bilateral fractures are often comminuted. With comminution of the bone, tension-band wiring can collapse the fracture fragments and result in imperfect reduction. In these cases, additional support is required and can be provided by the methods described next.

**ACRYLIC REINFORCEMENT OF INTRAORAL WIRING**

In comminuted fractures, where wiring causes collapse of the mandible, some method of buttressing the bone is required to maintain its length. The simplest method uses acrylic reinforcement of the wires.

After the wires are placed, an intraoral splint is made by molding acrylic around the interdental wires and contouring it to fit the mouth (Fig. 103-10). The acrylic conforms to either the roof or floor of the mouth from the caudal surface of the incisors to 306 or 406. The acrylic serves as a buttress to maintain length and alignment. Additional wires are placed across the soft acrylic through drill holes in the bone and are tightened when the acrylic has set.

The surgeon should ensure that the acrylic splint is as form-fitting as possible and uses the least amount of material to serve the desired purpose. Excessive acrylic material in
the mouth impedes eating by interfering with the horse’s tongue. Ideally, dental acrylic should be used, because it sets with no appreciable exothermic reaction.

A more precise fit of methyl methacrylate to the oral surface can be obtained by molding methyl methacrylate to the mouth as well as possible and allowing it to harden. The methyl methacrylate is removed after it has cured, and the shaping is finished with a rasp or dermal tool to remove excess material and round any sharp edges. After smoothing, holes are drilled in the splint for wiring to the mandible, premolars, and incisors as necessary. Wiring configurations vary with the individual fractures.7,8

**U-Bar Brace**

Bilateral fractures almost always require support in the form of an intraoral brace or external fixator in addition to tension band wiring to maintain axial alignment, limit side-to-side mobility, and prevent collapse2 (Fig. 103-11).

An intraoral splint is made from malleable brass or aluminum rods.9,10 The pre-bent U-shaped brace is placed on the buccal surface of the incisors and spans the interdental space and the entire length of the dental arcade bilaterally. The brace is adaptable to fixation of fractures of the mandible, incisive bone, and premaxilla. The brace bar is fixed to the incisors and cheek teeth in multiple sites by cerclage wires encircling the teeth and bar. Wiring to the incisors is accomplished using individual cerclage wires, each encircling an incisor and the brace. Wiring to the cheek teeth is accomplished via stab incisions through the cheek and drilling between the teeth at the gum line.

This splint is very stable but is quite time consuming to apply (Fig. 103-12). The splint can be aided by application of tension-band wiring as previously described.

**Intramedullary Pins**

Intramedullary pins can, in selected cases, be a useful adjunct in the repair of mandibular fractures.11 Indications for intramedullary pinning are rare, because pin placement options are limited by the tooth roots. Intramedullary pins provide axial alignment, and protruding pin ends can serve as fixation points for wires. When used alone, intramedullary pins are likely to migrate.

**Screws**

Lag screw fixation is used to repair selected fractures of the mandible in the region of the diastema and symphysis.5,12 Lag screw fixation is useful in this area, especially in adult horses, because the bone is strong enough for purchase of the screw threads, and the screws can be used under biomechanically favorable circumstances (see Fig. 103-9). Symphyseal fractures are, however, rare.

The fractures are reduced manually and held in reduction by pointed reduction forceps. A stab incision is made through the gingiva, and 3.5-mm, 4.5-mm, or 5.5-mm cortex screws are inserted in lag fashion across the fracture plane. At least two screws should be placed to provide rotational stability. Lag screw fixation is appropriate if the fracture configuration allows screw placement without damaging the teeth and there is adequate bone for purchase of the screws. Screws are not removed unless they become infected and are the source of persistent drainage.

A cortex screw may also be placed unicortically on each side of the fracture line such that the screw heads are used as an anchor for figure-eight wiring. This provides a simple, minimally invasive method for tension wiring of the body of the mandible. This method also poses little risk to the tooth roots when the screws are placed on the ventral cortex.

A 5- to 7-cm longitudinal incision is made directly over the fracture on the ventral surface of the mandible. The fracture is reduced, and a 4.5- or 5.5-mm cortex screw is placed approximately 2 cm from the fracture line. Figure-eight wiring is completed with 1.25-mm stainless steel wire looped under each screw head and twisted until tight. Cortex screws can be inserted on the lateral surface of the mandible if preoperative or intraoperative radiographs are used to plan screw placement.

**External Fixators**

External fixators are good options for repairing fractures of the ramus or body of the mandible, premaxilla, and maxilla.13,14 Advantages of external fixators include closed repair, reduced risk of sepsis to the fracture plane, easy removal of implants, and good stability. Disadvantages are additional technical expertise and the expense of additional equipment, potential of traumatizing tooth roots, and

![Figure 103-11](image-url)
frequent infection of pins associated with loosening. Intraoperative radiographic control is needed as well.

If a type II fixator is selected, each pin penetrates the medial and lateral cortex of both mandibles, and a connecting bar is placed on each side. Indications for a type II external fixator include bilateral fractures of the mandible or premaxilla or a highly unstable unilateral fracture (Fig. 103-13). Type II fixators are best applied with the horse in dorsal recumbency.

With type I external fixators, the pins engage both cortices of one side of the mandible. Indications would be a unilateral fracture of the horizontal ramus of the mandible. A type I fixator may be applied with the horse positioned in either lateral or dorsal recumbency. Ideally, at least two pins should be placed rostral and caudal to the fracture.

The usual pin size is 4 mm (\(\frac{5}{32}\) inch) in diameter, and a 6-mm (\(\frac{3}{16}\)-inch) diameter connecting bar is used. In type I fixators, positive profile end-threaded pins are preferred to standard smooth pins because of their increased holding power in bone and decreased risk of pin loosening. In type II fixators, positive profile center-threaded pins are preferred. The pin holes should be predrilled before inserting the pins. Holes are drilled starting with a 2.5-mm hole and sequentially enlarging it ideally to a size 0.1 mm smaller than the pin size, which provides perfect axial preload to ensure solid fixation within the bone.\(^{15}\) This type of drilling should be accompanied by continuous flushing of the drill bit to reduce heat production, which will prevent premature pin loosening caused by thermal necrosis of bone. High-torque, low-speed drills or hand drills are preferred to minimize thermal damage.

Steinmann pins are inserted through both cortices of both mandibles via stab incisions in the skin. Radiographic assistance is used to place the pins either ventral to, or between, tooth roots. Pin placement perpendicular to the sagittal plane prevents the pin from angling in either a rostral or caudal direction and damaging a tooth on the opposite mandible. All pins should be inserted in the same
horizontal plane to facilitate placement of the connecting clamps and rod.

An alternative technique that allows more variation in pin placement and is more forgiving of imperfect pin placement is to use an acrylic side bar. This obviates the need for all pins to be in the same plane. An acrylic side bar can be constructed with a piece of flexible rubber hose (25 mm inside diameter). The hose is skewered by the pins. The ends of the hose are occluded, and the lumen is filled with liquid polymethylmethacrylate, which is allowed to harden. An acrylic side bar can be molded to fit closer to the horse’s head, which decreases the likelihood of inadvertently catching the fixator on objects in the stall. However, an acrylic side bar cannot be adjusted should the need arise.

A variation of this method involves opening the hose over the whole length (see Fig. 103-13). Wire is subsequently looped around the pins and tightened the same way as described for tension wiring of the teeth. This compresses the fracture, resulting in greater stability. The hose is then closed with parm bands, and the hose is filled with acrylic, as described earlier.

PINLESS EXTERNAL FIXATOR

A pinless external fixator attaches to the mandible via clamps instead of conventional transcortical pins (Fig. 103-14). This technique offers the advantage of a type I external fixator without the risk of damaging the tooth roots with pin placement. Clamps are made in a symmetric configuration with trocar-type points for attaching to the mandibular symphysis and an asymmetric clamp configuration with one trocar point and another bifurcated tip for fastening to the body of the mandible. Stab incisions are made in the soft tissues, and the tips of the bone clamp are embedded in

**Figure 103-13.** Type II external fixator is placed across both rami of the mandible. A tension-band wire is applied around the pins and tightened to achieve interfragmentary compression of the fracture. The previously open soft tubes are closed with parm bands, and the lumen is filled with epoxy material (e.g., polymethylmethacrylate, hoof acrylic).

**Figure 103-14.** Pinless external fixator applied to a mandibular fracture. a, asymmetric clamp attached to the ramus; b, small adjustable connecting rod; c, single external fixator clamp; d, tubular connecting bar, which fits into the clamp (c).
the mandibular cortex by an applicator instrument. Clamp placement avoids soft tissue structures and tooth roots because the clamps attach only to the cortex. Connector rods, clamps, and a rigid side bar complete the type I external fixator configuration.

Use of the pinless external fixator has been described in the horse and in adult cattle. It may be applied to add stability to a fracture treated with wires and/or a bone plate during the initial postoperative period (Fig. 103-15). The benefits of this device include lack of pin tract infections, avoidance of traumatizing tooth roots, and flexibility for selecting the application point. One disadvantage is the increased cost; however, these clamps can be reused several times, partially offsetting the purchase costs.

With either method of external fixation, daily pin tract care is required to prevent soft tissue infection. The pin–skin interface should be cleaned as necessary and antibiotic ointment and a bandage should be applied.

External fixators can inadvertently catch on objects in the horse’s environment. This problem is minimized by fitting the fixator as close to the horse as possible, wrapping the fixator to cover areas prone to snagging, and stabling the horse in an area free of projections.

**Plates**

Bone plates are used for repair of fractures of the ramus and body of the mandible. Plating has several disadvantages that limit its usefulness for repair of fractures of the horizontal ramus of the mandible. Plates must be placed on the ventrolateral or lateral surface of the mandible. Exposure of the ventrolateral mandible is complicated by the presence of the parotid salivary duct. Screw placement is difficult because of the tooth roots. There is little soft tissue to cover the plates on the ventrolateral aspect of the mandible. Also, most fractures of the mandible are open, communicate with...
the oral cavity, and result in contamination of the implants, which necessitates their eventual removal.

Nevertheless, there are indications for bone plates. Fractures of the horizontal ramus of the mandible involving the caudal cheek teeth and body of the mandible are difficult to repair with intraoral wiring procedures because of limited exposure. Severely comminuted fractures might benefit from bone plates used in buttress fashion. Broad or narrow 3.5-mm limited-contact dynamic compression plates (LC-DCPs) or reconstruction plates or 4.5-mm LC-DCPs with at least three screws on each side of the fracture are desirable. In selected cases, long plates are used and screws are inserted in selected holes along the plate.

Compression plating is an option for fractures of the horizontal ramus of the mandible in the interdental space (Fig. 103-16). Locking compression plates (LCPs) can improve stability of the fixation when used farther caudal (Fig. 103-17). However, the most appropriate indication for the use of bone plates is closed fractures of the body and vertical ramus of the mandible. Horses demonstrate less pain and return to feed quicker when these fractures are stabilized. These fractures are usually closed and have adequate soft tissue covering. The tooth roots do not pose an obstacle to screw placement in this area.

A skin incision is made along the caudal edge of the mandible that parallels the caudal border of the mandible. In that location, the masseter muscle can be avoided and there is abundant bone to allow solid insertion of the screws. The lateral aspect of the vertical ramus is extremely thin and does not accept 4.5-mm screws. Smaller screws may be used, but the implants are not strong enough to withstand the cyclic loading occurring during chewing food. Additionally, the facial nerve and the transverse facial artery and vein are located superficially on the lateral aspect of the ramus.

A large periosteal elevator is used to expose the caudal rim of the vertical ramus. A plate spanning the fracture and providing three to five screw holes on either side is selected (Fig. 103-18). Selecting a longer plate allows the surgeon to choose which plate holes to use. In selected cases, wire sutures may be used to appose fracture lines on the lateral surface of the ramus through small incisions (see Fig. 103-18). The plate is contoured to the surface of the bone and applied using routine technique. The subcutaneous tissues and skin are reapposed over the plate, with sutures in two separate layers.

A study has compared dynamic compression plate (DCP) fixation of an osteotomy in the diastema of the mandible with a fixation using an external fixator and interdental wiring and an intraoral splint and interdental wiring. This study revealed that DCP fixation had the greatest stiffness under monotonic bending to failure; however, the relatively low yield value might predispose it to earlier failure in fatigue testing without supplemental fixation.19 The techniques using tension-band wiring in conjunction with an external fixator or an intraoral splint were similar to DCP constructs in yield, failure, and osteotomy displacement, whereas the external fixator constructs alone were biomechanically inferior to all others.

DCP fixation is therefore most likely the most stable form of fixation for comminuted fractures of interdental spaces.19 However, for simple interdental space fractures, intraoral splinting together with interdental wire fixation should provide adequate stability with minimal invasiveness and decreased expense. Tension-band wiring significantly enhances the strength of type II external skeletal fixators and should be used to augment mandibular fracture repairs.19

**Aftercare**

Horses seldom demonstrate a reluctance to eat after fractures are stabilized, and they are quickly returned to routine feeding. The incisors are used only in prehension of food materials, and mastication is performed by the cheek teeth.2 No attempt to modify the diet is made following repair of incisor fractures. Fractures involving the cheek teeth could give the horse more difficulty during mastication.

Horses should be provided a palatable diet that can be easily chewed. They usually prefer customary foodstuffs to the gruels and mashes sometimes recommended during convalescence. Therefore, there is little need to modify the diet unless there is a clear indication that the horse is having difficulty in masticating.

All foodstuffs tend to accumulate around the intraoral wires, rods, and acrylic. Frequent garden hose lavage of the mouth to remove accumulated debris is beneficial if the horse will tolerate it.

Phenylbutazone is routinely administered at 4.4 mg/kg by mouth for 7 days. The decision to administer antibiotics...
is made on an individual basis. Most fractures are open and contaminated and benefit from administration of broad-spectrum antimicrobial agents.

Removal of the implant is usually carried out on the standing patient after healing has occurred, usually in 6 to 8 weeks. Bone plates and buried cerclage wires are not customarily removed unless the implants become infected.

**Complications**

Implants should be inspected regularly because wires loosen and break. Loose wires may be tightened by additional twisting. Undetected loosening of implants can result in malocclusion and delayed healing because of instability. The decision to replace broken implants should be based on the timing of implant failure. The wires can be removed if

---

**Figure 103-17.** A, Ventrodorsal radiograph showing the mandible in a foal after it was kicked in the jaw 3 weeks earlier. Two fractures with marked medial displacement (two arrows) are shown in the left hemimandible with an additional fracture in the right (one arrow). The fracture caused the rostral mandible to deviate to the left. B, Ventrodorsal, and C, lateromedial postoperative radiographs. The bone had partially healed and was refractured and repaired with a four-hole 3.5 locking compression plate (LCP) and a five-hole 3.5-mm reconstruction LCP. Note the slight caudal displacement of the mandible. The fixation healed without complications, and the implants were removed 5 weeks later.
the fracture is stable at the time of breakage. Failures that occur earlier in the postoperative period require replacement to maintain alignment and stability.

Drainage from the fracture is common following repair of open fractures, because infection is always present after exposure to the oral cavity. In most cases, the infection resolves with systemic antimicrobial agents and effective drainage. Drainage that persists for more than 4 weeks should be investigated.

With closed repair of comminuted fractures, small fragments of avascular bone commonly become sequestra. Radiographs should be taken to confirm the presence of sequestra if drainage persists. In many cases, the sequestra can be removed by curettage in the standing patient if the fragments are superficial.

Callus formation is to be expected with secondary bone healing of infected fractures and is more prominent with fractures that occur in the horizontal ramus of the mandible, because there is less soft tissue coverage. Factors that increase callus formation are comminution, infection, and instability in the repair. Efforts to attenuate these factors are rewarded with a more cosmetic outcome.

Prognosis
The prognosis for a serviceable outcome is favorable in most cases. Imperfect reduction of fractures leads to malocclusion. Fractures of the teeth themselves and fractures involving the alveolus sometimes result in tooth loss. Tooth loss (when it occurs) and irregular tooth wear because of malocclusion are managed effectively by regular dental care.

FRACTURES OF THE SKULL AND SINUSES
Fractures of the skull and sinuses are the result of blunt trauma from being kicked or from collisions. The most commonly injured bones include the nasal, frontal, and maxillary bones and the zygomatic process of the frontal bone. The trauma that causes fractures to these bones can cause damage to the brain, eye, and nasal passages, resulting in severe hemorrhage. Depression fractures are often found.

Diagnosis
Initially, a minimally displaced depression fracture can be difficult to detect on physical examination because of the soft tissue swelling that obscures the depression. Other signs include obvious bone displacement, epistaxis, and skin lacerations. Emphysema can be palpated in the soft tissues as crepitus when fractures communicate with the nasal passages or sinuses. Radiographs with multiple oblique views are necessary to demonstrate the fracture. Computed tomography aids greatly with the final diagnosis and preoperative planning of the repair. Physical examination should include endoscopic examination of the upper airways as well as neurologic and ocular examinations to assess for additional undetected trauma.

Treatment
Initial therapy should be directed toward stabilizing the patient (see Chapter 8), because in most cases there is no urgency in the repair. In fact, fracture repair is often difficult if significant soft tissue swelling has developed, and therefore repair is best delayed until swelling resolves. Skin lacerations should be repaired immediately to prevent infection to the soft tissues, even if fracture repair is delayed. Hypersomotic wound dressings applied under pressure wraps will dissipate the edema. Phenylbutazone is administered to decrease inflammation, and antimicrobial therapy is indicated for any open fractures or fractures that communicate with the sinuses. Tetanus prophylaxis is indicated in all cases.

Trauma to the facial bones often results in hemorrhage into the sinuses, which shows up on a lateral radiograph as a fluid line within the sinus. Consideration should be given
to standing sinus lavage for removal of accumulated blood, when present, to prevent empyema of the sinus. Lavage is performed via an ingress portal made with a 6-mm (½-inch) Steinmann pin inserted into the frontal sinus and polyionic fluid lavage with a pressurized fluid delivery system.

Repair should be performed as soon as the soft tissue swelling is resolved. Delay in repair beyond a few days can result in difficulty in achieving reduction. The goals of repair are to maintain a patent airway and nasolacrimal duct, prevent ocular damage, and obtain a cosmetic appearance. Cosmetic considerations are the main purpose of repairing fractures that do not impair other body systems.

The typical configuration is a segmental depression fracture. Often, the skin and periosteal attachments are intact. Even so, the fractures usually communicate with the nasal passages or sinuses and will be contaminated, so that infection of soft tissues and of implants could be a problem. Therefore, the surgical approaches should be performed as minimally invasively as possible to visualize the fracture, achieve reduction, and apply the implants. Many fractures can be reduced through stab incisions with no stabilization beyond that provided by the soft tissue attachments.

Adequate reduction can often be achieved by elevating the fragments and wedging them back into place. Whenever possible, closed reduction should be performed. The soft tissue attachments provide vascularity and the means for stabilizing the fractures once they are reduced. Adequacy of fracture reduction can be ascertained by direct inspection or evaluation of the facial contour; this is the reason for allowing the soft tissue swelling to resolve before attempting any repair. The depressed fragments can be elevated by drilling holes in the bone and inserting an elevator to pry the fragment back into place. A disadvantage of this approach is that commercially made elevators typically have a broad, flattened shaft that requires large drill holes to insert into the bone.

A better way to elevate the fracture fragment involves drilling a hole into the depressed segment with either a 3.5-mm drill bit or a Steinmann pin on a Jacobs chuck. A 4-mm (⅜-inch) diameter Steinmann pin can be bent and inserted into the hole to elevate and wedge the fragment back into place. The end of the pin is bent at a right angle so that when the pin is inserted into the bone drilled in the fracture segment it has a broad area of contact and added leverage for elevating the fragment (Fig. 103-19). The length of the bent end should approximately match the width of the depressed bone segment. Another right angle bend is made in the opposite end of the pin to make a handle. Axial traction is applied to pull the fragment back into place.

The skin over the drill holes is closed with a single suture. If necessary, multiple drill holes can be made with little or no disruption of the soft tissue attachments. In most cases the fragments can be wedged into place with no additional stabilization required because the fractures are not load bearing. If the fractures do require stabilization to maintain reduction, wire sutures can be applied in selected locations around the fragment. A small skin incision is made to expose the fracture line. A Steinmann pin (1.6 mm) and hand chuck or 2-mm drill bit is used to pre-drill holes for 0.8- to 1.0-mm cerclage wire sutures (see Fig. 103-19). Skin closure is routine.

Occasional indications for the use of reconstruction plates arise with severely comminuted or unstable fractures. These plates are made in a variety of shapes and sizes and are easily contoured to fit specific fracture configurations.

**Aftercare**

Postoperatively, a pressure bandage is applied, and phenylbutazone is administered to decrease postoperative swelling and discomfort. Broad-spectrum antimicrobial agents are administered as necessary to treat soft tissue and sinus infections and prevent implant infections.

**Complications**

Inadequate reduction results in an inferior cosmetic outcome. Secondary bone healing results in callus formation, which causes an obvious blemish when it occurs over areas with no muscle. This is, however, only of temporary duration, because once the fracture is healed remodeling of the callus occurs, normalizing the contours of the skull. Hemorrhage into the paranasal sinuses can develop into a sinus empyema if untreated. Stenosis of the nasal passages can occur with severe injuries; however, this is rare. If the fragment is denuded of its blood supply through a loss of the peristeum, sequestration can occur, but it is less frequent than with mandible fractures.

When a sunken appearance is evident after healing because of inadequate reduction of depressed fragments or in cases that were left untreated (Fig. 103-20), refracture and proper alignment is not easily accomplished. The facial contour can be restored by implantation of prostheses of either a silicone or a fluorocarbon polymer and carbon fiber combination. General anesthesia and strict asepsis are required.

With either technique, a slightly curved incision is made over the defect to expose the sunken bone. The implant material is sculpted to fill the defect and restore the normal facial contour. The silicone prosthetic material is sutured in place between the periosteum and the skin. A subperiosteal washout and suction is performed, followed by a subperiosteal fluid lavage with a pressurized fluid delivery system.
dissection is performed for insertion of the fluorocarbon polymer–carbon fiber prosthesis between the bone and periosteum. Skin closure is routine.

**Prognosis**

The prognosis for return to previous level of performance is usually good. The cosmetic outcome depends on the reduction achieved at surgery and is usually acceptable and often excellent depending on the severity of the injury.

**PERIORBITAL FRACTURES**

Fractures of the orbit are common in horses. The orbit serves as a protective housing for the eye and associated adnexa. The orbit consists of the lacrimal, frontal, and zygomatic processes of the frontal and temporal bones. Fractures are the result of direct trauma and are usually of the depression type. Concurrent injury can be sustained to the central nervous system, eye, lacrimal duct, other skull bones, and the paranasal sinuses. These structures warrant examination as part of the physical examination prior to repair.

**Diagnosis**

Diagnosis is made by physical examination. Abnormal facial contour, soft tissue swelling, crepitus, and hemorrhage are usually present. Acute soft tissue swelling can obscure the fracture and make detection difficult by physical examination alone. Pain can preclude a thorough physical examination in the unsedated patient.

Radiographs are indicated to identify trauma to the orbit but are also useful to identify concurrent injury and problems such as fluid in the maxillary sinuses. Fractures of the zygomatic arch are visible on the appropriate views; however, trauma to other parts of the orbit are difficult to image on radiographs. Oblique views at different, sometimes acute, angles are often necessary to highlight the fractures. Ultrasonography might allow diagnosis of fractures and of tissue injuries lying deeper in the orbit.

The extent of ocular trauma is variable and ranges from chemosis to rupture of the eye. A thorough ocular examination should be performed, including an assessment of the patency of the lacrimal duct when fractures of the lacrimal bone are present.

**Treatment**

Fractures will heal without surgery, but in most cases they are associated with a facial deformity. Surgical repair is indicated to relieve impingement to the eye. Injury to the eye is treated as circumstances warrant (see Chapter 63). Repair is best attempted as soon as the patient is stabilized. The goal of reconstruction is to relieve impingement on the globe and adnexa and restore the normal anatomic contours to achieve a cosmetic outcome. There are no muscle attachments to the orbit, except the small palpebral muscles that are inconsequential to any repair undertaken. Fractures often need only to be realigned to heal properly. It is important to palpate the inner surface of the orbit to identify and remove any bone fragments that can damage the eye. These fragments are very difficult to identify with radiographs.

Fractures of the orbit that involve the zygomatic, lacrimal, or frontal bones are usually depression fractures and may be treated by elevation of the fragments via drill holes in the depressed segment as described in the previous section. Zygomatic process fractures may be reduced noninvasively by use of a bone hook. The horse is prepared for surgery with the affected side up. A finger is inserted into the orbit in the conjunctival space to palpate the fracture and guide the placement of a bone hook onto the ventral surface of the displaced fragment. Dorsal traction is used to elevate and wedge the fragment back into anatomic alignment (Fig. 103-21). Fractures of more than 48 hours’ duration are more difficult to reduce.

Most fractures are sufficiently stable that no other form of fixation is required. Fractures that do not maintain alignment after reduction require some form of stabilization in addition to that provided by the soft tissue attachments. These fractures are usually comminuted or involve portions of the orbital rim other than the zygomatic arch. Open reduction and interfragmentary wiring is the easiest but not the strongest method to provide additional stability when needed.

An incision is made directly over the fragments to be wired. Holes are drilled into the bone with a 2-mm drill bit. Cerclage wire of 0.8-mm to 1.0-mm diameter is pre-placed and twisted to tighten.

Reconstruction plates can be used to repair severely comminuted fractures of the zygomatic arch (see Fig. 63-11).
These plates have the advantage of being easily contoured. Bone plates should be reserved for cases in which easier methods will not achieve a satisfactory result.

Aftercare
Phenylbutazone is administered postoperatively to decrease discomfort and soft tissue swelling. Antimicrobial agents are not required if the fracture is reduced noninvasively. Systemic antibiotic agents should be administered if the fracture is open or communicates with the maxillary sinus, or if implants are used. Pressure bandages are not used because of the eye. Selection of any topical medication, if needed, should be based on safety of the substance for use in the eye.

Complications
Periorbital fractures are often associated with trauma to the eye. Rupture of the eye, proptosis, corneal ulceration and laceration, chemosis, and damage to the nasolacrimal duct are reported complications. Empyema of the maxillary sinus can occur secondary to hemorrhage into the sinus.

Prognosis
Healing of the fractures usually proceeds uneventfully. The cosmetic appearance depends on the accuracy of surgical reduction and the amount of callus but is usually good. A prognosis for associated ocular trauma depends on the nature and severity of the injury.

RESECTION OF THE ROSTRAL MANDIBLE, PREMAXILLA, AND MAXILLA
Ossifying fibromas of the rostral mandible are the most common indications for a rostral mandibulectomy (Fig. 103-23, A). Other neoplasms, such as adamantinomas, and fungal and parasitic diseases can also be indications for the procedure. Inadequate local excision of these lesions results in a recurrence; therefore, block excision with wide non-affected margins is required. This procedure was developed in an attempt to completely excise the lesions in one surgical intervention.

Surgical Procedure
The animal is anesthetized and placed in dorsal recumbency on the surgery table. The endotracheal tube is placed either through the nasal passages or via a temporary tracheotomy, facilitating unimpeded access to the mouth. The oral cavity is washed, making sure that the cuff of the endotracheal tube is tight and prevents fluids from entering the lungs. The jaws are spread and maintained in that position by carefully placing a speculum between the cheek teeth. The dorsal aspect of the oral cavity and the upper lip is draped. A transverse incision is made in the oral mucosa on the lingual side of the incisors. The gingiva is incised on the labial surface of the incisors ventral to the lesion, and this
incision is continued laterally and dorsally on both sides to connect with the initial incision. Both incisions are thus connected and continued down to the bone on the mandibular symphysis.

The soft tissues are elevated and reflected caudally with a periosteal elevator on the mandibular symphysis to expose normal bone. The soft tissues are preserved to allow coverage of the exposed mandibular stump.

The mandibulectomy procedure involves removing the incisive bone and as much of the symphysis of the mandible as needed, taking into account that part of the symphysis should be saved to ensure rostral continuity of the mandible. An oscillating bone saw or Gigli wire is used to transect the mandible at the selected level. After the bone edges are rounded off, the soft tissue on the lingual surface of the mandible is folded rostrally over the exposed mandible and trimmed to fit the mucosal flap from the labial surface (see Fig. 103-23, B). A Penrose drain is placed between the bone and the soft tissues.

Closure is performed to prevent the sutures from being subjected to trauma during mastication. An acceptable cosmetic appearance is retained as well as the ability to prehend feed despite significant shortening of the mandible (Fig. 103-24).

A similar procedure for excision of the premaxilla and maxilla caudal to the canine teeth has been described. 28

Complications and Prognosis

For both procedures, a recurrence of the lesions can only be prevented by completely resecting them. The cosmetic outcome is acceptable to many owners.

Flaccidity of the lower lip may occur with rostral mandibular resection. Horses have no difficulty with prehension of hay and grain; however, they may have difficulty with prehension of short grass. Protrusion of the tongue may occur. 29

WRY NOSE (CAMPYLORRHINUS LATERALIS)

This condition is present at birth and is assumed to be a congenital disorder. In Arabian horses it is possibly genetically linked, because of its frequency in this breed. 30 Intrauterine positioning as an etiology of this deformity is only a theory.

The foal is presented within the first few days to weeks after birth because of the cosmetic appearance. Clinically, a varying degree of premaxillary deviation is noticeable upon inspection of the foal's head; the deviation often results in malocclusion, with no contact between the incisors of the mandible and maxilla (Fig. 103-25). One side of maxilla or premaxilla is dysplastic, resulting in the lateral deviation toward this side. Often there is also a certain rotational component in the deviation. Close observation also reveals
Figure 103-23. A, Preoperative picture of a 9-year-old Belgian horse with an ossifying fibroma of the mandible. B, Postoperative appearance after a partial rostral mandibullectomy. Note that the mucosa was sutured over the cut surfaces of the mandible.

Figure 103-24. A, Lateromedial radiograph of an adamantinoma at the rostral end of the mandible (arrows). B, Postoperative radiograph showing the missing rostral aspect of the mandible. C, Despite the mandibulectomy, the horse maintained an acceptable cosmetic appearance.
an enhanced concavity of the hard palate in the interdental space region.

An incongruity of the nostrils and nasal septum are an additional anomaly. Some foals experience breathing difficulties or have increased respiratory sounds.

This condition will not self-correct, and a decision should be made to treat the foal using reconstructive techniques or to euthanize it to prevent it from suffering.

**Surgical Procedure**

Surgical correction should be delayed until the foal is 2 months old to allow the maxilla to gain enough strength to accept implants. The foal is anesthetized and positioned in dorsal recumbency on the surgery table. The endotracheal tube is inserted, the cuff is inflated, and the mouth is thoroughly washed.

Because the nasal septum is involved in the deviation, it is best to perform a resection of 8 cm of the rostral nasal septum at the onset of the surgery. This eliminates resistance against correction after the bilateral osteotomy of the maxilla. The nasal passages are packed with gauze sponges soaked in antiseptic solution. A surgical approach to the interdental space is made and the maxillary periosteum is elevated.

With an oscillating saw or a Gigli wire, both rami of the maxilla are transected. To achieve symmetry of the upper and lower jaws and normal interdental contact, the incisors of the maxilla and mandible should be temporarily wired shut. An individual wire brace is applied to the incisors of the mandible and maxilla respectively (see Figs. 103-2 and 103-3). Prior to tightening of the wire loops around each tooth, a double strand of wires is alternately pulled in a simple continuous fashion between the mandible and maxilla. The individual wires in the mandible are now tightened, followed by the wire loops in the maxilla. Lastly, the ends of the double-stranded wire suture between the incisors of the mandible and maxilla are connected and solidly tightened, effectively preventing opening of the mouth.

In the next step, 3.2-mm Steinmann pins are inserted from the rostral aspect of the mandible in a caudal fashion crossing the osteotomy sites, providing stability to the maxilla. The application of an autogenous cortical bone graft in the form of a rib has been described in the literature. An alternate approach is to apply locking compression plates (see Fig. 103-17).

The wiring of the tooth arcades ensures anatomic reconstruction and is maintained until the osteotomies have partially healed and can provide some stability. Enteral nutrition is provided for the foal (see Chapter 6), often by milking the mare and administering the milk through a stomach tube. Half of the packing of the nasal passages is removed one day postoperatively and the second half one day later. Some asymmetry of the rostral part of the nose will persist.

This correction can be performed without wiring the teeth; however, there might be inadequate stability across the osteotomy sites. In that case, the foal should be prevented from eating hay and grain.

**Complications**

Postoperative infection of the surgery sites and breakdown of the fixation are the most serious complications. Depending on the severity and duration of the problem, euthanasia of the patient has to be considered.

**TEMPOROMANDIBULAR JOINT DISORDERS**

Temporomandibular disease is diagnosed more often now than in the past. Different signs are being recognized, including reluctance to eat, attitude changes, and asymmetry of the head. Care must be taken to look at the entire head. An asymmetry can be caused by muscle atrophy or a swelling on the affected side. Sometimes it is difficult to recognize which side is involved without diagnostic imaging techniques. Most information can be gained from computed tomography (CT) (Fig. 103-26) or magnetic resonance (MR) imaging.

As expertise in the diagnosis and management of temporomandibular joint (TMJ) disorders increases, more techniques are being developed to treat them. In the future, arthroscopic techniques might be used to salvage the joint before radical surgical procedures are used. A recent cadaveric study demonstrated that a good portion of the TMJ can be evaluated arthroscopically.

**Infection**

TMJ sepsis is rare in horses. However, standard diagnostic aids used to diagnose joint infections can be applied to the TMJ (see Chapter 88 for details).
Arthroscopic investigation of the dorsal joint pouch of the TMJ can be performed through a stab incision into the dorsocaudal compartment. One report has described successful management of a septic TMJ with mechanized resection of synovium and fibrinous debris, copious lavage, and intra-articular and systemic antibiotics. Eight months postoperatively, there was no clinical evidence of osteoarthritis or ankylosis of the TMJ.

Condylectomy of the Mandible

Mandibular condylectomy is an option for treatment of fractures through the TMJ that are not amenable to repair. An alternate indication is management of osteoarthritis of the TMJ that causes chronic pain. However, additional work is needed to find a practical solution to salvage the TMJ with osteoarthritis.

Surgical Procedure

A condylectomy is performed in lateral recumbency under general anesthesia. A 6-cm horizontal skin incision is made, centered on the TMJ, extending rostrally and curving medially, caudal to the mandibular condyle. The soft tissues are reflected ventrally to expose the joint capsule.

The TMJ is opened by a horizontal incision of the joint capsule. The periosteum on the condyle is incised vertically, and a periosteal elevator is used to reflect the periosteum both rostrally and caudally. An oscillating bone saw or Gigli wire is used to make a 2-cm deep cut in the mandibular condyle 2.5 cm ventral to the articular surface (Fig. 103-27).

A chisel is inserted into the osteotomy and pried dorsally to fracture off the lateral portion of the mandibular condyle. It is necessary to remove the lateral portion of the condyle before continuing the cut through the condyle to provide room to introduce scissors to cut the capsular attachments. The oscillating saw is used to continue the osteotomy through the remaining portion of the mandibular condyle. The condyle is grasped with forceps for removal, and any joint capsule attachments are cut with scissors. The meniscus is removed by incising its attachments with scissors. The bone edges are rounded.

Closure is performed in three layers: the periosteum and joint capsule, the subcutaneous tissue, and the skin. Additional information on temporomandibular joint disorders are found in Chapter 30.

Complications and Prognosis

The results of mandibular condylectomy have been summarized for normal horses. Remodeling of the condyle resulted in the formation of a pseudo-condyle with satisfactory function. There are no reports of its use in clinically affected horses. Short-term complications in normal horses included masseter atrophy, malocclusion, weight loss, and difficulty inprehension and mastication.

Radical Mandibular Excision

Neoplasia of the mandible is the indication for a radical mandibular resection. Tumors of the body of the mandible are rare and difficult to treat surgically. One report describes en bloc resection of the horizontal ramus of the mandible for excision of a malignant tumor. The mandibular defect is bridged using a bone plate of appropriate length as a buttress placed on the ventral surface of the mandible. A type II external fixator is used for additional support. The few occasions in which this type of treatment has been attempted makes formulation of a prognosis difficult.

References

the flow of information is depicted as DNA. Crick described the paradigm of molecular biology in which information flow, and gene function fell into place. In 1958, DNA was identified, the mechanisms behind inheritance, which are located in the cell nucleus. Once the structure of organisms, most of the DNA is found in the chromosomes, cells that make up plants, animals, and other multicellular genetic code for every living organism. In the eukaryotic acid. DNA is the elementary template carrying the essential determine the true crystalline structure of deoxyribonucleic process. In 1953, Watson and Crick were the first to studies of the structure, function, and reactions of DNA, RNA, proteins, and other molecules in connection with life processes. In 1958, Watson and Crick were the first to determine the true crystalline structure of deoxyribonucleic acid. DNA is the elementary template carrying the essential genetic code for every living organism. In the eukaryotic cells that make up plants, animals, and other multicellular organisms, most of the DNA is found in the chromosomes, which are located in the cell nucleus. Once the structure of DNA was identified, the mechanisms behind inheritance, information flow, and gene function fell into place. In 1958, Crick described the paradigm of molecular biology in which the flow of information is depicted as DNA $\rightarrow$ RNA $\rightarrow$ protein. DNA is replicated (i.e., DNA is synthesized from DNA), whereas RNA is transcribed from DNA. It is called transcription because the same type of "language" is used in DNA as in RNA—that is, nucleic acids. In some cases, RNA may be used to make complementary DNA (cDNA) (i.e., reverse transcription) using a particular enzyme called reverse transcriptase. Protein is synthesized from messenger RNA (mRNA) by translation. This is called translation because a different language is used—that is, amino acids instead of nucleic acids. Once protein has been synthesized from RNA, the information is trapped. In other words, there is no known mechanism that allows information to flow back into RNA from protein.

Thousands of genes are being discovered for the first time by sequencing the genomes of model organisms, a reminder that much of the natural world remains to be explored at the molecular level. With the recent completion of the sequencing of the different genomes, it appears that now a map of a defined being exists. In a genetic map, the location of the genes is assigned to the different chromosomes. A gene is the functional and physical unit of heredity passed from parent to offspring. Most genes contain the information to synthesize a specific protein. However, it is the proteins of those genes that interact with each other in the context of a cell (or more appropriately, in the context of a whole organism, unicellular or multicellular). In eukaryotes, certain proteins are targeted to particular compartments within the cell (e.g., organelles (such as mitochondria), endoplasmic reticulum). Where a particular protein will go can be predicted by the signal sequence that is encoded by the gene. However, a genetic map by itself cannot describe how proteins will interact with one another.

Genomics refers to the study of genes and genomes, whereas proteomics is the study of proteins (i.e., protein structure and function, and their interactions in an organism). Now that several genomes have been sequenced, research focuses on protein structures and interactions (primarily for the purpose of medically relevant information).

Molecular techniques alone, however, are not sufficient to explain complex cell mechanisms, which always warrant a combination of biochemistry, chemistry, and other life science fields such as cell biology. Molecular techniques used for applications in cartilage resurfacing or bone augmentation and enhancement usually involve scientists who provide basic scaffolds or carriers for tissue engineering and engineers who construct the necessary bioreactors where tissues are grown in vitro. Molecular techniques have led to explanations of how biomechanical forces (e.g., compression, strain, tension) induce signaling pathways on a cellular level in fibrous tissue, cartilage, bone, and tendons. Almost 110 years after Wolff wrought "the law of transformation of bone according to mechanical load," molecular biology provided the foundation to understand what causes this transformation on a molecular level.

The introduction of molecular biology into the field of musculoskeletal research has opened new avenues for understanding the pathophysiologic of musculoskeletal structures, including bone, cartilage, tendons, periosteum, paratenon, and perimysium. Through molecular techniques, signal pathways and signal molecules involved in synthesis and degradation of matrix macromolecules can be identified and manipulated for diagnostic and therapeutic purposes. For example, once the pathway of pathologic articular cartilage degradation is better understood, the use of molecular techniques aimed at downregulating DNA/RNA expression of degradative protein concentrations, and the use of knockout or transgenic mice to upregulate protective mechanisms, will be possible. Furthermore,
molecular technology has provided novel therapy through the use of genetic vectors,\textsuperscript{15,25-28} application of growth factors,\textsuperscript{29,30} and the implantation of tissues grown in vitro (e.g., for cartilage resurfacing).\textsuperscript{1} Growth factors are used to influence multipotent stem cells in vitro and in vivo to facilitate differentiation of cells in a desired direction, or to discourage de-differentiation of cell lines or tissue-engineered products.\textsuperscript{31}

**INTERACTION OF DIAGNOSTICS AND RESEARCH**

The introduction of molecular biology has made it possible to study cellular mechanisms in tissues harvested from patients, either from biopsies or during surgery. Recently, the search for biomarkers that allow early detection of, for example, cartilage destruction, fracture healing, and bone resorption has become very popular, not only in research\textsuperscript{34} but also in clinical settings.\textsuperscript{35,36} For example, antibodies against epitopes in degraded collagen type II or cleaved procollagen fibrils can be measured in synovial fluids of patients\textsuperscript{35,36} as well as in dissolved cartilage tissue, cell, or explant cultures. Antibodies against epitopes (BC-3, epitope 846) of proteoglycans\textsuperscript{38,39} allow the measurement of glycosaminoglycan (GAG) concentrations. Similarly, the enzymatic activity of matrix metalloproteinases, nitric oxide, prostaglandin (PG) E\textsubscript{2}, and GAG concentrations are being studied for their suitability as biomarkers to predict early cartilage degeneration in equine patients.\textsuperscript{40-42} Some of the most useful methods for diagnosis of and research into musculoskeletal disorders are described here.

**Methods of Detecting Gene Regulation**

**Analysis of the DNA/Genome: Whole Genome Application**

Advancements in technology have made it possible to sequence the bases in a section of the DNA of any organism in a short time. The purpose of such sequencing is to determine the sequences of the chemical base pairs that make up DNA, to store this information in databases, and to identify all genes in a desired species. The DNA Isolation Kit for Cells and Tissues permits the rapid, large-scale isolation of DNA from cells and tissues. Even small amounts of tissue such as those found in thin sections can be used. Several procedures provide a quick, easy, and safe method for removing contaminating RNA and proteins, resulting in purified genomic DNA ranging in size from 50 to 150 kilobases (kb). The procedure includes sample homogenization followed by cellular lysis, in the presence of a strong anionic detergent and protease K. RNA is eliminated with an RNase treatment, and proteins are removed by selective precipitation and centrifugation. The purified DNA is subsequently recovered by isopropanol precipitation.

To understand the role and function of genes, complete information on their RNA transcripts and proteins is needed. Unfortunately, exploring protein functions is difficult because of their complicated and unique three-dimensional structures and the lack of efficient technology. To overcome this difficulty, a technique is used that focuses on the mRNA molecules produced by the genes of interest (gene expression), and this information is used to investigate the functional roles of the genes. This idea stimulated the development of the micro-array technique—a method to study the interactions between thousands of genes based on their mRNA transcript level.

DNA micro-arrays provide a natural vehicle for the exploration of genome-wide surveys of gene expression patterns or functions. The results should be viewed as maps that reflect the order and logic of the genetic program rather than as the physical order of genes on chromosomes (genetic map). Exploration of the genome using DNA micro-arrays and other genome-scale technologies should improve our knowledge of gene function and molecular biology.

Applications of micro-arrays range from the study of gene expression in different tissues under different environmental stress conditions to the comparison of gene expression profiles for tissues with pathophysiologic changes. This approach involves the use of fluorescently labeled reverse transcribed mRNAs (also called complementary DNA [cDNA]), which contains only the coding part of the sequence, complementary to its corresponding mRNA transcript. Micro-arrays are a form of microscopic chip containing hundreds to thousands of immobilized DNA samples. The main function of a micro-array chip is to detect and quantify the concentration of a specific mRNA transcript or its cDNA respectively. The chips are overlaid in a solution containing the fluorescently labeled cDNAs to allow them to hybridize with their complementary DNA sequences, previously placed on the micro-array chip. Because the cDNA on the chip is fluorescently labeled, every spot emits light in the ultraviolet spectrum corresponding to the amount of hybridized cDNA. The variable intensity of the ultraviolet dye at different spots allows the comparison of the gene expression patterns under different experimental conditions (case-control studies). The hybridized array is typically scanned with a system that uses lasers as a source of excitation light and photomultiplier tubes as detectors. This system is capable of differentiating the fluorescently labeled probes. Initial data obtained from DNA micro-arrays are in the form of scanned images. Coding the gene expression by means of colors can be helpful for building genetic maps and graphic data processing. An expression gene map is presented in the form of a table, the rows of which correspond to the consecutive genes and columns representing different samples, such as under multiple experimental conditions or for different patients.

This approach provides a way to directly use the growing body of sequence information for parallel experimental investigations. Because of the combinatorial nature of the chemistry and the ability to synthesize small arrays containing hundreds of thousands of specifically chosen oligonucleotides, the method is readily scalable to monitor tens of thousands of genes simultaneously. After the scanning of the micro-array chips for fluorescence, a grid must be placed on the image and the spots representing the arrayed genes must be identified. The data must be normalized to allow a comparison of the separate arrays. With multiple experimental conditions (e.g., time-points or drug doses), the genes are often grouped into clusters that behave similarly under the different conditions. Gene clusters are visualized with trees or color-coded matrices by placing genes with similar patterns of expression into a clustered group.
Several providers manufacture arrays to monitor the global activities of genes. In addition, custom expression arrays can be designed for other model organisms, proprietary sequences, or specific subsets of known genes. For human arrays, expressed sequences from databases are collected and clustered into groups of similar sequences. Using clusters as a starting point, sequences are further subdivided into subclusters representing distinct transcripts. This categorization process involves alignment to the human genome, which reveals splicing variants.

Presently, apart from the human and mouse genome, an equine-specific gene chip is being developed for research purposes offering up to 3000 equine genes normally involved in musculoskeletal diseases (Affymetrix, Santa Clara, Calif, is presently developing a Genechip System).

**Analysis of the DNA Genome:**

*Gene-Specific Applications*

Micro-array analysis of gene expression does have limitations. They include the impact of mRNAs that are spliced alternatively or the limited ability to detect unstable mRNAs. Therefore, differential gene expression results must be confirmed through direct examination of selected genes. These analyses typically occur at the level of RNA blot or quantitative real-time polymerase chain reactions (qRT-PCR) to examine transcripts of a specific gene. The technique of qRT-PCR is a powerful method for studying gene expression in various species and tissues. Competitive PCR for quantitative measurement of absolute levels of mRNA molecules has been applied to different genes and species. Moreover, total RNA isolated from individual microbiopsy samples may be successfully used for microarray-based gene expression analysis of any discretely localized cellular group, which can be identified functionally or morphologically.

In many laboratories, these technologies are being used to detect gene regulation of disease after treatment with stimulating or inhibiting substances. Northern blots, followed by densitometry measurements or the more advanced TaqMan system, are used. For both techniques, mRNA probes (of about 100 to 120 base pairs) have to be developed out of cDNA using reverse transcription methods based on the isolation of total mRNA from the specific tissues in question.

Obtaining high-quality, intact RNA is the first and often the most critical step in performing many fundamental molecular biology experiments. The isolation and use of purified RNA in the laboratory is complicated by the fact that, chemically and biologically, RNA is significantly more labile than DNA. The choice and optimization of RNA purification methods are important for successful isolation of quality RNA and consistent performance of downstream applications. To avoid damage or loss of RNA, nuclease contamination of the RNA samples during preparation and handling should be avoided. The process of isolating intact total RNA from certain tissues is even more difficult. Fibrous tissues and tissues rich in protein are challenges for total RNA isolation because of the DNA and nuclease present. These tissues require more manipulation during the RNA isolation procedure. Finding the most appropriate method of cell or tissue disruption for the specific starting material is important for maximizing the yield and quality of RNA preparation.

Research into optimizing RNA analyses has identified two points in the RNA isolation process that can be improved: treatment and handling of tissue or cells prior to RNA isolation, and storage of the isolated RNA. During tissue disruption for RNA isolation, it is crucial that the denaturant be in contact with the cellular contents at the moment the cells are disrupted. This is difficult to achieve when the tissue and cells are hard (e.g., bone) and when samples are numerous, making rapid processing difficult. A common solution to these problems is to freeze the tissue/cells in liquid nitrogen or on dry ice. The samples are then ground with a mortar and pestle into a fine powder, which is added to the denaturant. This freezing and grinding process allows the postponement of RNA isolation, but it is time-consuming and laborious. The last step in every RNA isolation protocol, whether for total or mRNA preparation, is to resuspend the purified RNA pellet. After carefully preparing an RNA sample, the RNA is suspended and stored in a safe, RNase-free solution.

Therefore, on a practical level, whenever tissues from patients or experimental animals are harvested with the aim of isolating mRNA levels, collection has to occur without delay at surgery, after euthanasia, or after slaughter, and tissues need to be preserved immediately. Apart from the freezing of the tissues as just described, storage of the tissues for PCR in RNAlater (Qiagen, Valencia, Calif), has worked well in the authors’ laboratory for cartilage and soft tissue. The tissue should be no thicker than 0.5 cm and should be kept in no less than 10 μl RNAlater per milligram of tissue. The tissues should be stored at +4°C for 24 to 48 hours for fixation, and afterward stored at −20°C, where they are stable indefinitely. If this method is chosen, it is not necessary to use liquid nitrogen or to store at −80°C. To extract the RNA from fibrous tissue, cartilage, and bone, Trizol combined with the RNeasy kit (Qiagen) in a Polytron mixer works well in the authors’ experience. When preparing samples for testing using PCR, tissue should be handled with sterile instruments and surgical gloves (without glove powder).

**In Situ Hybridization on Microscopic Sections**

The qRT-PCR, cDNA, and RNA micro-arrays make it possible to follow the presence of, and the gene expression patterns in, tissues from clinical patients, explant cultures, or specific cell lines in cell cultures. With the exception of the cell culture systems, however, they do not allocate certain gene patterns to one specific cell type at a particular location. For example, if cartilage tissue harvested en bloc from a joint is minced, and total RNA is extracted for qRT-PCR to assess the expression of matrix metalloproteinases (MMPs), it is not possible to track down the upregulation of MMPs to the superficial, middle, or deep zone of the entire cartilage. The data will show only that mRNAs of particular genes are upregulated in the cartilage.

In some instances, however, it is important to know which cell type regulates these gene patterns and, above all, where it is regulated, to understand the whole cascade of events. For this, the technique of in situ hybridization can be used. Although this technique can be used for localizing DNA, it usually is applied for detection of mRNA. Specific
RNA probes are hybridized to mRNA directly in tissue sections and visualized with special detection systems. The mRNA probes are ideally longer (about 400 to 600 base pairs) compared with the qRT-PCR or micro-array techniques and are coupled to the detection systems. These can consist of fluorescent substances, digoxigen, or radioisotopes (\(^{35}S, ^{32}P, ^{3}H\)). In the case of digoxigen, a secondary antibody is normally used for detection of the probes (e.g., alkaline phosphatase), whereas for visualization of radioisotopes, techniques similar to autoradiography are applied. The technique of in situ hybridization is quite demanding and its successful use depends on the individual tissue and probes. Whereas in cartilage, muscle, or other soft tissue related to the musculoskeletal system, it can be relatively easily performed, application in bone structures is very difficult. In situ hybridization for cartilage and soft tissue can be performed using either frozen (cryosections) or paraffin-embedded tissue sections. In the latter, only small tissue samples should be prepared, which are fixed in buffered, freshly made 4% paraformaldehyde for only a short time (30 minutes to 12 hours). The ideal time has to be determined for each particular probe and tissue section. If tissue is fixed too long in paraformaldehyde, the collagen linkage may be too strong for the probe to penetrate the tissue and hybridize the mRNA in question. This may lead to false interpretations. Therefore, it is wise to run qRT-PCR parallel to or even in advance of in situ hybridizations.

Alternative studies often include alteration of gene function with targeted gene deletion by the application of RNA interference (RNAi) on the cellular level. Posttranscriptional gene silencing or RNAi is the technique in which introduction of a double-stranded RNA (dsRNA) suppresses the expression of the homologous gene. Longer dsRNA molecules are reduced in vivo to 21- to 23-nucleotide small interfering RNAs (siRNAs), which are the mediators of the RNAi effect. Introduction of 21 nucleotides siRNAs with two nucleotide 3’ overhangs does not stimulate the antiviral response in mammalian cells and can effectively target specific mRNAs for gene silencing. Such molecules can be prepared by chemical synthesis or in vitro transcription. Being a highly specific and efficient knockdown technique, RNAi not only is a powerful tool but also holds promise for gene therapy. The interesting biology as well as the remarkable technical value has been drawing widespread attention to this exciting new field.

### Methods of Detecting Proteins

In gene expression, the correlation between induced mRNA and induced levels of protein is not always clear. Translational and posttranslational regulatory mechanisms that impact the activity of various cellular proteins are not examined by DNA micro-arrays, although the emerging field of proteomics is beginning to address this issue.

### Analysis of Proteins: Global Analysis

Proteomics is the study of the overall protein content of a subcellular compartment, cell, tissue, or organism at a particular moment in time and under certain environmental conditions. There are more proteins than genes in an organism by orders of magnitude. On the basis of alternative splicing (several per gene) and posttranslational modifications (over 100 known), there are estimated to be a million or more different proteins. Proteomics is a powerful field of study to compare different states of a biologic system—for example, normal versus diseased. The success of proteome analysis is largely built on three techniques: two-dimensional (2D) polyacrylamide gel electrophoresis, mass spectrometry (MS), and genomic sequences.

A broad range of technologies are used in proteomics, but the central paradigm has been the use of 2D gel electrophoresis (2D-GE) followed by mass spectrometry (MS). 2D-GE is used to first separate the proteins by isoelectric point and then by size. Individual proteins are subsequently removed from the gel, prepared, and finally analyzed by MS to determine their identity and characteristics. Various types of mass analyzers are used in proteomics MS. The recent development of soft-ionization techniques, namely matrix-assisted laser desorption ionization and electro-spray ionization, have allowed large biomolecules to be introduced into the mass analyzer without completely decomposing their structures, or even without breaking them at all, depending on the design of the experiment.

### Analysis of Specific Proteins

Protein function refers to the variety of mechanisms by which proteins are activated or inactivated in vivo. The study of protein function includes assays to detect and quantitate the activity of specific proteins in vitro and in vivo. With the emergence of functional proteomics in the postgenomic era, an expanded view of protein function exists, with each protein operating as a component of an intricate web of interacting molecules.

To study protein function, purified proteins may be delivered into cells to determine the conditions under which they are active. Signal transduction, the communication of extracellular signal to intracellular activation of proteins, may be examined by specific detection of activation states of key regulatory proteins.

### Detection of Protein Expression Levels

Antibodies (monoclonal and polyclonal) have been successfully applied in musculoskeletal research. Antibodies allow following signaling molecules on a protein level—that is, assessing whether translation into proteins has occurred. Depending on the antibody and available commercial tests, the identification and determination of concentrations of certain proteins can be conducted by Western blot or ELISA. Unfortunately, commercially available antibodies and ELISA are normally designed for antibodies in humans, mice, rats, or rabbits and may not be valid for use in equine tissues. However, in molecules where high homology is conserved between species, antibodies may cross-react with antibodies from humans, rats, or mice. Furthermore, if money is available and collaborations are sought with molecular biology departments, antibodies and ELISA can be custom designed for equine patients.

Antibodies also make it possible to label cells, since many cells expose specific CD receptors at their surface (e.g.,
cultures or living animals. The latter, however, is applied to model systems, such as pro-collagen, and to demonstrate the activity of a constitutive activated promoter that is randomly incorporated in the genome and later can be visualized by confocal imaging and fluorescence microscopy. To study the insertion of a reporter plasmid carrying the green fluorescent protein (GFP) reporter gene under the control of an inducible nitric oxide synthase [iNOS] inhibitor, compared with the untreated wt mice, or in wt mice treated with a potent iNOS inhibitor, compared with the untreated wt mice.

Animal experiments with genetically modified mice have clarified cell mechanisms in the musculoskeletal system. However, the bone structure of rodents is different from that of other animals and, therefore, results have to be interpreted with some caution. Rodents seem to be more sensitive than other animals in their response to fracture healing, the application of growth factors, and heterotopic

Cellular Analysis

Cell sorting based on labeling of specific cell structures has become routine in cell biology. Sophisticated machines allow identification of cells according to previously applied labels. In addition to the FACS cell sorter (Becton-Dickinson), there is a flow cytometer by Coulter Electronics and the MoFlow by Cytomation. They all use the technique of flow cytometry to quantify components or structural features of cells, primarily by optical means. Although the measurements are made on one cell at a time, the machines process thousands of cells in a few seconds. The cells may be alive or fixed at the time of measurement, but they must be in a monodispersed (single-cell) suspension. The sample is passed through a laser beam in a continuous flow of a fine stream of the suspension. Each cell scatters some of the laser light, and it also emits fluorescent light excited by the laser. Light scatter alone is often quite useful. This technique is commonly used to exclude dead cells, cell aggregates, and cell debris from the fluorescence data. Light scatter has been used in the authors’ facility to quantitate aggregation of living cells.

Fluorescent probes are used to study the quantities of specific components of cells, whereas fluorescent antibodies are used to study the densities of specific surface receptors and thus to distinguish subpopulations of differentiated cell types, including cells expressing a transgene. By antibodies fluorescent, the binding of hormones to surface receptors can be measured. Intracellular components can also be determined by fluorescent probes, including total DNA per cell (allowing cell cycle analysis), newly synthesized DNA, specific nucleotide sequences in DNA or mRNA, filamentous actin, and any structure for which an antibody is available. Flow cytometry can also monitor rapid changes in intracellular free calcium, membrane potential, pH, or free fatty acids.

Methods Involving Whole Animals

Molecular biology can be used to investigate gene function in living animals. Through genetic and appropriate breeding manipulations, either knockout or transgenic mice with overexpression of a certain gene are produced. Depending on the importance of the gene in body function or morphology, these mice may not grossly differ phenotypically from their normal siblings (the wild type [wt] mice). These knockout or overexpression mice are usually recognized by an addition to their homozygous or heterozygous state (−/−, +/+). If these animals are compared with their wt groups, the effect of a gene can be studied, especially after stimulation with critical substances. For instance, it was demonstrated that the development of collagen-induced osteoarthritis was delayed in iNOS knockout mice, or in wt mice treated with a potent iNOS inhibitor, compared with the untreated wt mice.

Animal experiments with genetically modified mice have clarified cell mechanisms in the musculoskeletal system. However, the bone structure of rodents is different from that of other animals and, therefore, results have to be interpreted with some caution. Rodents seem to be more sensitive than other animals in their response to fracture healing, the application of growth factors, and heterotopic

CD44). For example, to find out which cell types are involved in certain tissue reactions, tissues are digested, and the cells are carefully isolated, labeled with specific antibodies, and subjected to fluorescence-activated cell sorter (FACS) analysis (see later). The FACS machine sorts cells according to their label and displays their distribution in the cell suspensions.

Immunohistochemical techniques are used to demonstrate antibodies bound to antigen in tissue sections. A secondary antibody directed against the antigen-specific antibody coupled with a fluorescent dye, digoxegenin, biotin, or avidine generates a strong signal and thus allows visualization of the distribution of the antigen in the tissue section using a light microscope. Immunohistochemistry is used to type collagen (collagen types I, II, III, IX, or X), to detect the epitopes of collagen degradation or cleavage products of procollagen, and to demonstrate the presence of MMPs 1, 2, 3, 8, 9, and 13, and their tissue inhibitors (TIMP) in different cartilage zones.

Depending on the homology of proteins between species, antibodies can be used across species (e.g., antibodies to inducible nitric oxide synthase [iNOS], prostaglandin [PG] E2, factor VIII, tumor necrosis factor [TNF]-α). The pitfalls are unexpected cross-reactions and misinterpretation of data. If antibodies have not been validated for horses beforehand, the surgeon should collaborate with immunologists. It should be determined in advance whether the antibodies can be used in paraffin sections or cryosections (further detail follows).

Detection of Enzymatic Activities

Sometimes it is not possible to visualize or measure proteins from tissue or body fluids using antibodies because the proteins are either inactive or irreversibly bound through other proteins. It may also be that the protein is ubiquitously present in a latent form but is only of interest in an activated form. For example, some MMPs are irreversibly bound by either α-microglobulins or TIMP-1, 2, or 3. In these cases, it is possible to use fluorescein quenchers bound to a peptide, which release the fluorescein upon degradation and thus give an indirect measure of the enzyme’s activity.

Several methods are available to study the multiplication or expression of a certain protein or cell, such as bromodeoxyuridine labeling of proliferating tissue or bioluminescence imaging using luciferase with either cell cultures or living animals. (The latter, however, is applicable only in laboratory mice.) Another possibility involves the insertion of a reporter plasmid carrying the green fluorescent protein (GFP) reporter gene under the control of a constitutive activated promoter that is randomly incorporated in the genome and later can be visualized by confocal imaging and fluorescence microscopy. To study the incorporation of a plasmid and the later expression on a transcriptional level, plasmids encoding enhanced GFP can also be introduced into cells and followed by visualizing the expression of GFP with fluorescent microscopy.

Apart from studying proliferation of cells or expression of proteins, these methods may also be used to track migration of cells within specific tissues.
bone formation or cartilage healing of defects. Some reported results obtained in rodents were not repeatable in higher animals and thus may have created some confusion in the field of bone enhancement.

Difficulties Related to Hard Tissue Structures

Although these molecular biologic and immunohistochemical methods are routinely used in soft tissue without difficulty, their use in cartilage and bone is more complex. The isolation of RNA from cartilage and bone tissue can prove tricky because of the low number of cells per sample weight and the heavy interference of the extracellular matrix. This is especially true for bone, for which double or triple the amount of tissue must be used and extra purification steps are needed if routine RNA isolation kits are used. Automated isolation procedures for obtaining total RNA can be used for cell cultures of osteoblasts and chondrocytes only, not for bone or cartilage tissue. Bone and cartilage tissues must be manually ground using a plotter, which is time consuming.

Problems also arise when using immunohistochemical and in situ hybridization methods for cartilage and bone of animals other than laboratory mice and rats. As long as cartilage samples can be embedded in paraffin, routine immunohistochemistry and even in situ hybridization procedures can be conducted. However, if cryosections are required, problems may be encountered related to the attachment of the sample to the glass slide. In these cases, there should be extra cartilage sections in reserve. Immunohistochemical and in situ hybridization methods in undecalcified bone samples of horses embedded in plastic sections have proved to be impossible in the authors’ laboratory, even if special acrylic resins as embedding medium are used (LR-White, Polyscience, UK; Histodur, Leica, Switzerland). Although these materials may be sufficient for rodents and small dogs and cats, they are not hard enough for horse (or sheep) bone to be cut in thin sections. In addition, epitopes may be distorted or hidden in the plastic embedding media, so that no reactions can occur despite prior deplastification of the sections. As for in situ hybridization, the probes may be too long to penetrate the tissue in the plastic, and they are hindered by the hydroxyapatite crystals. Recommended decalcification methods using 4% to 14% ethylenediaminetetra-acetic acid (EDTA) for horse (or sheep) bone samples render the material does not allow cutting thin slices (2 to 3 mm) in a fresh-harvested state. The use of formic acid for decalcification is time consuming. Although these molecular biologic and immunohistochemical methods are routinely used in soft tissue without difficulty, their use in cartilage and bone is more complex.

Molecular Biology in Clinical Therapy of the Musculoskeletal System

Molecular biology has gained wide acceptance for therapeutic interventions in the musculoskeletal system. The delivery of recombinant growth factors (e.g., bone morphogenetic protein [BMP]-2) to enhance defect healing in cartilage or bone has finally become a clinical reality, at least in humans where cost issues are not as prohibitive as in veterinary medicine. The possibility of using recombinant technologies to produce these factors has further stimulated this type of research for clinical applications. For many years, a single growth factor was sought as a solution for delayed fracture healing or nonunion. More recently, however, researchers have fine tuned this type of biological enhancement so that combinations of growth factors and timely sequences as well as release patterns are sought after. Biotechnology, an emerging field in musculoskeletal research and in clinics, generally involves a combination of molecular technology (mostly growth factors and DNA plasmids), natural or synthetic scaffolds or carrier substances, appropriate release systems, and engineering in the form of bioreactors with or without mechanical stimulation and final implantation in the body system. Molecular techniques are used to produce the appropriate growth factors applied in these systems, and to investigate the cellular synthesis of macromolecules under these conditions. It was shown for cartilage and vertebral discs created in bioreactors that functional loading during in vitro incubation increased the production of extracellular matrix significantly. In fact, transplantation of cartilage discs created in vitro has already become a clinical reality, used in focal cartilage lesions, such as in osteochondritis dissecans lesions in humans.

Importance of Biomaterials

Biomaterials play a major role in the field of biotechnology apart from cell culture methods with the appropriate cell culture media and incubation conditions for different cell types (e.g., bioreactors, mechanical stimulation). Bioresorbable materials, such as tricalcium phosphate (TCP), or similar ceramics, scaffolds based on polyglycolic or lactic acids, polyester urethane foam (DegraPol), and other materials, are often used for cell seeding or incorporation of substances that enhance tissue healing. The biocompatibility of the biomaterials—not only the finished product but also the intermediate degradation products—must be tested for toxicity and
tissue-specific immunologic reactions while the scaffolds are being resorbed.\textsuperscript{88} Immediate, short-term, and long-term results of biomaterials in the tissues must be investigated to avoid unpleasant surprises.

Purified silk is a new alternative to one of the oldest surgical materials.\textsuperscript{94} Silk used as suture material is accompanied by modest inflammatory reactions, but new molecular techniques allow purification of the fibroin fibers, leading to a highly biocompatible biomatrix for synthetic replacement of bone, ligaments, tendon, and possibly (in the future) cartilage.\textsuperscript{5,95-97} Using purified silk is an innovative approach that means that the same scaffold material can be adapted to the local requirements in strength, structure, pore size, and composition. Furthermore, it can be modified by adding release systems and additional structural components such as crystals (for example, in bone).

Recently, hydrogels have been successfully introduced as carrier matrices for bone- and cartilage-enhancing substances, without or in combination with calcium phosphate granules.\textsuperscript{75,98-100} Calcium phosphate is needed for structural purposes, because defect healing in bone may not be achieved with bone-enhancing substances alone. However, linking bone-enhancing substances to the hydrogels allows retracted release of the molecules, and it thus avoids premature clearing of the substances from the field of action.

Additional information about biomaterials is presented in Chapter 9.

**Growth Factors**

Several techniques have been used successfully to enhance bone and cartilage healing with growth factors, mostly in mice, rats, and rabbits.\textsuperscript{102-104} and considerably less in higher animal species.\textsuperscript{105,106} The synthesis of growth factors has been greatly facilitated by recombinant technology in molecular biology, which made it possible to seek commercial applications in tissue healing, mainly in bone and cartilage. Platelet-derived growth factor (PDGF), acid and basic fibroblast growth factor (FGF), insulin-like growth factor (IGF)-II, transforming growth factor (TGF)-β, and BMPs are the most widely used. Among these, the BMP family is probably the most established and meanwhile also is clinically applied grouping humans and animals (Genzyme, Cambridge, Mass). Some of these factors (TGF, IGF, BMP) are abundantly present in bone matrix, and others occur naturally during fracture healing (PDGF, FGF).\textsuperscript{107,108} These growth factors appear in concert and in a timely sequence, which may be one of the reasons that surgical application of just one factor in a relatively high concentration may not be as beneficial for bone healing in higher animals as originally hoped. Therefore, modern approaches concentrate on combinations of growth factors, careful selections of dosages, and respect for the natural sequences of these factors.

In recent years, it was demonstrated that low doses of parathyroid hormone (PTH) applied systemically could counteract the negative effects of osteoporosis in postmenopausal women.\textsuperscript{109} As a consequence, the local application of PTH\textsubscript{1-34} incorporated in a fibrin-based hydrogel structure with granules consisting of a mixture of tricalcium phosphate/hydroxyapatite (HA/TCP)\textsubscript{β} at a 60%-to-40% ratio was investigated in a critical mid-shaft tibia defect in experimental sheep (Kuros Biosurgery, Switzerland). A dose-dependent increase of callus formation and bridging of the original defects could be demonstrated, with the best results being close to the gold standard, the autogenic bone grafts\textsuperscript{108} (see Chapter 92).

**Release Systems and Drug Delivery**

As when only a single growth factor was applied, results were discouraging if growth factors were injected locally in the form of proteins via a single dose at the time of the initial surgery or during fracture healing. This was attributed to the fast clearance of the growth factor through the local vasculature, and a short incubation time with the local cells. Therefore, release systems were studied that allowed protracted or burst releases of these growth factors at later times.\textsuperscript{32,75,98,109,110} Microspheres consisting of polyglycolic acid are capable of directing the local release of BMP-2\textsuperscript{110} and IGF-II\textsuperscript{112} and improve results considerably. Along the same line, nonviral vectors, such as liposomes or magnetofection are reported in the literature for enhancing bone healing, although only in experimental animals.\textsuperscript{111-113} Drug delivery is possible using polymer nanoparticles or superparamagnetic iron oxide nanoparticles (SPIONs) coated with a suitable polymer (dextran, silicon, PVA, PEI) that are functionalized with either pharmaceutical substances, proteins, or peptides, and also DNA plasmids.\textsuperscript{114,115} If plasmids are delivered with SPIONs, the process is called magnetofection.\textsuperscript{111}

**Gene Transfections**

Gene transfections using viral and nonviral vectors have been attempted in synovial membranes of horses, and also in equine chondrocytes in culture.\textsuperscript{116-119} For therapeutic purposes, an attempt has been made to introduce plasmids into the genomic information of these cells to affect their biologic behavior. These gene transfections can be performed in vivo or ex vivo.\textsuperscript{120} In the latter method, autogenic cells are harvested from the animal, kept in culture under appropriate conditions, transfected using a viral or nonviral vector, and finally reintroduced into the site of harvest. For example, the gene transfection of equine synovial membranes with interleukin-1 receptor antagonist (IL-1ra) by means of an adenoviral vector inhibited the development of osteoarthritis in an established equine model of osteoarthritis.\textsuperscript{118}

**Pitfalls of Molecular Biology Techniques in Therapeutic Interventions**

Molecular biology techniques have a place in musculoskeletal research but not yet in equine therapy. The cost is prohibitive for veterinary medicine. Also, clinical reports in which healing of cartilage or bone after application of growth factor could not be seriously demonstrated or could not be repeated, raised criticism of their use. Finally, the long-term effects and safety issues of the application of growth factors (proteins, peptides, or plasmids) are
controversial. Research must focus on these issues before safe and routine clinical use can be advocated.

Potential of Applying Molecular Biology in Musculoskeletal Research

Although molecular biology is still an emerging field in musculoskeletal research, the tools are established in diagnostics and increasingly becoming so in basic clinical research. Recombinant technology allows the development of equine-specific gene chips and antibodies that will open avenues in musculoskeletal research. Some techniques have to be adapted and modified in hard tissues such as calcified cartilage and bone, but the potential benefit for important research in the field of cartilage and bone development is unlimited. In fact, this technology makes it possible to answer research questions that could not be solved with other methods, and to use tissues harvested from patients to explain pathophysiologic mechanisms leading to disease. In addition, this technology can save lives of experimental animals, since diseased tissues of patients can be compared with controls without having to conduct animal experiments. Studies of tissues harvested from subchondral cystic lesions in horses during surgery are an example. Incubating tissues as explant cultures, the determination of proinflammatory and local mediators, and measuring the regulation of cytokines IL-1 and IL-6 using qRT-PCR and in situ hybridization demonstrated the inflammatory nature of the lesions without sacrificing horses as experimental animals.12,13 (see Chapter 92).

The future of molecular biology techniques in equine therapy, possibly in combination with surgery or chemotherapy, is promising. Already, treatment of equine melanomas with cytokines,12,13 or filling surgically débrided cystic lesions with hydrogels enriched with bone-enhancing molecules,14-16 points to a successful clinical application. Research of the musculoskeletal system depends on collaborations with scientists from other fields. Surgeons interested in clinical research in this field need a solid background in molecular biology, biochemistry, and cell biology. Graduate courses and postgraduate training are mandatory. This field of research has a great potential to change the future of musculoskeletal diagnostics and therapy in horses and humans.

As in all vertebrate species, the skeleton is a major component of the horse's body, since it provides structural protection to the internal organs and rigid links for muscular attachment to allow for muscle action and body movement. It also acts as a reservoir for calcium and phosphorus—a dynamic mineral reserve. Bone is the principal component of the skeleton, and it is composed of an orderly deposition of mineral on an organic matrix substrate giving it the viscoelastic properties required to serve its function.

Bone has many unique features that allow it to fulfill these functions. It is the third hardest substance in the body, after dentin and enamel. Bone has orderly micro- and macro-structural properties that are constantly turned over in response to physical and biochemical demands. Bone is a highly vascular tissue with an excellent capacity for self-repair. In this chapter, the structure and function of bone including its biomechanical characteristics and the specific forces that lead to particular fracture types is discussed. The necessity for establishing stability after fracture and the biologic reaction and healing of bone, including how to clinically evaluate a fracture's healing to determine when to remove external coaptation or to return a horse to exercise, is described.

**STRUCTURE AND FUNCTION OF BONE**

Macroscopically, bone can be divided into two broad types, compact or cortical bone and cancellous or trabecular bone. Compact bone is present in the shafts of the long bones, whereas cancellous or trabecular bone occupies the cavities within bone that contain either hematopoietic or fatty marrow. Cancellous bone is composed of a fine network of interlacing partitions called trabeculae, and it is found in most of the axial skeleton and in the ends of the long bones.

The appendicular skeleton generally consists of long cylindrical structures with narrow, predominately cortical midsections. The relatively long length of equine bones increases the moment arm of each limb, enhancing a horse's power and speed. The expanded ends of the bones distribute stresses across the joint surface, thereby diminishing the loads to the articular surface.

All long bones, except regions covered by articular cartilage or where ligaments, tendons, or joint capsules are attached, are covered by periosteum (Fig. 80-1). Periosteum is made up of two layers: an outer fibrous layer that acts in a supportive capacity, and an inner osteogenic layer that provides the cells necessary for fracture healing, or that during growth is responsible for appositional bone formation before skeletal maturity. In immature animals, the osteogenic layer of the periosteum is thick and highly vascular. As the animal matures, this layer thins and becomes only loosely adhered to the bone.

On a microstructural level, bone can be divided into three principal components that are intimately associated with each other to allow rapid responses to both the mechanical and the homeostatic requirements of the body. These components are the cells, the organic extracellular matrix, and the inorganic portion of bone.

Of the cellular component, osteoblasts, osteocytes, and osteoclasts are the predominant cell types in bone. Osteoblasts develop from fibroblastic osteoprogenitor or mesenchymal cells and cover the majority of bone surfaces. They are responsible for the formation of the organic matrix of bone called osteoid. Osteoblasts deposit osteoid on bone surfaces, incorporating themselves in osteoid seams. Approximately 10% of the osteoblasts become enclosed in matrix and are then referred to as osteocytes. Compared with osteoblasts, osteocytes have less endoplasmic reticulum and fewer cytoplasmic organelles. They have numerous cytoplasmic processes that extend into the matrix and fill the canaliculi of bone (Fig. 80-2). These processes contact adjacent osteocyte processes and osteoblasts to form an intricate transport and communication system within bone. This interconnecting framework regulates the flow of mineral ions from the extracellular space surrounding the osteoblasts to the osteocytes and then from the osteocytes to the extracellular fluid surrounding them. This arrangement allows the large surface area of the osteocyte population to regulate mineral ion exchange between the extracellular fluid and the bone by the canicular system.
Osteoclasts are the cell type responsible for the majority of bone resorption. These cells are large, multinucleated, and are found on or near bone surfaces that occupy concavities on their surface called Howship’s lacunae. Osteoclasts originate from blood monocytes, which arrive at their destination in bone through the vascular system. Osteoclasts produce acid phosphatase and collagenase to first dissolve mineral and then to remove the organic matrix underneath the cells. In the extracellular space between the osteoclasts and the surface of the bone, both hydroxyapatite crystals and collagen fibers can be observed; they are degraded and taken up via endocytosis, transported across the cell, and finally extruded into the extracellular space.

The organic extracellular matrix is composed principally of collagen, proteoglycans, and glycosaminoglycans. Overall, the organic matrix makes up approximately 21% of bone by wet weight, with the remainder of the bone composed of inorganic material (71%) and water (8%). Of the organic matrix, 95% is collagen, with type I collagen being the predominant type. Collagen is the most abundant protein in mammals, accounting for 20% to 50% of the dry weight of adult long bones. Type I collagen is exceedingly strong in tension and is composed of three tightly folded polypeptide chains called α-chains (Fig. 80-3). The basic unit of collagen is tropocollagen, which is composed of three procollagen polypeptides coiled into a left-handed helix, and they are further coiled around each other into a right-handed triple helix. Triple helical collagen molecules polymerize into larger collagen fibrils with covalent bonds and cross-links forming between these molecules, adding to the fibrils’ high tensile strength. Individual α-chains of type I collagen consist of repeating tripeptides of glycine, proline, hydroxyproline, and hydroxylysine. Glycine accounts for approximately one third of all constituent amino acids in type I collagen because it is the only amino acid small enough to fit into the center of the triple helix of collagen.

The remaining 5% of the organic matrix in bone is ground substance, consisting of proteoglycans and glycosaminoglycans. Proteoglycans are high-molecular-weight substances or molecules that provide flexibility and resilience to the connective tissue matrix. Proteoglycans are made up of a central core protein, with glycosaminoglycan side chains that are attached covalently. These side chains are composed of repeating basic and acidic disaccharides. In addition to serving as the major constituent of the side chains of proteoglycans, glycosaminoglycans also serve as the cementing substance between layers of mineralized collagen fibers in lamellar bone.

The inorganic portion of bone consists primarily of calcium and phosphate, mainly in the form of hydroxyapatite crystals. The combination of the triple helical structure of type I collagen in intimate apposition with the small crystals of hydroxyapatite is responsible for the bone’s mechanical strength.

**BIOMECHANICAL DEFINITIONS**

The strength and stiffness of bone are its most important mechanical properties, and they can be assessed best by evaluating the response of bone to externally applied forces called loads. When these forces act on a structure like bone, deformation occurs, which is defined as a change in dimension such as decreased or increased length. When a load is applied to a structure, the deformation of the structure can be measured and plotted on a load-deformation curve. A typical load-deformation curve is illustrated in Figure 80-4. The initial linear portion of the curve, called the elastic
as it responds to externally applied loads. The two basic localized change in dimension that occurs within a structure expressed as force per unit area. Strain is defined as the plane that passes through a point in the body, and it is also absorption of the bone as it is loaded. Plastic deformation). The area underneath the curve defines the energy the curve (before the yield point, e, which is the change from elastic to plastic deformation). The yield point results in plastic deformation of the structure. Deformation within the elastic region of the curve is defined as plastic, and that which occurs in the plastic region of the curve is defined as plastic deformation. A ductile material has the ability to deform plastically to a great extent before fracturing. In contrast, a brittle material can sustain very limited strain prior to fracture.

The mechanical properties of bone differ significantly between the two macroscopic bone types. Cortical bone is stiffer than cancellous bone and fails at approximately 2% strain, whereas cancellous bone fails at 75% strain. Cancellous bone has the ability to store significantly more energy prior to failure than cortical bone, because of its ductility. Cortical bone tends to be a fairly brittle material and by definition can sustain only limited strain before fracture. Bone as a structure performs differently depending on the orientation of loading. For example, bone is significantly stronger in compression than in tension, a property known as anisotropy. In contrast, a material that exhibits neither structural orientation nor dependency on loading orientation is said to be isotropic.

**Figure 80-4.** Typical load-deformation curve of a viscoelastic substance such as bone. The ultimate failure point (f) is the load at which fracture occurs. The stiffness of the structure is the slope of the elastic region of the curve (before the yield point, e, which is the change from elastic to plastic deformation). The area underneath the curve defines the energy absorption of the bone as it is loaded.

**Figure 80-5.** Typical stress–strain curve of a bone sample. The slope of the linear elastic region of the curve defines Young's modulus in tension and compression and the shear modulus in pure shear.
The biomechanical response of bone to load depends on many factors including the geometry of the bone, the loading mode applied (for example, tension, compression), the material properties of the bone, and the frequency of loading. During normal daily activities, bone is subjected to various loading conditions including tension, compression, bending, shear, torsion, and, in many instances, a combination of these loads (Fig. 80-6).

During tensile loading, equal and opposite loads are applied to the ends of the structure, resulting in tensile stresses and strains within the structure. Maximal tensile stresses occur on a plane perpendicular to the applied load and tension. Tensile loading both lengthens and narrows the bone. Failure results from osteons debonding along cement lines; causing osteon pullout. Typically, tensile loading results in transverse fractures as occur in the proximal ulna, the proximal sesamoid bones, the patella, and the calcaneus (Fig. 80-7). Tensile fractures occur along the plane of maximal tensile stress, which is usually transverse to the tensile load.

When a bone is loaded in compression, equal and opposite loads are applied at the end of the structure, resulting in compressive stresses and strains (see Fig. 80-7). Maximal compressive stress occurs on a plane perpendicular to the applied load. In contrast to a bone’s response to tensile loading, the bone shortens and widens under compression, with failure occurring obliquely through the osteons, corresponding to the plane of maximal shear stress (at a 45-degree angle to the orientation of the compressive load). The bone fails along the maximal shear-stress plane because bone as a material is strongest in compression and weakest in tension, with shear strength being intermediate between compressive and tensile strengths. Pure compressive fractures are rare in horses but include Y-shaped fractures of the distal humerus and femur.

Bending, a very common loading mode in the appendicular skeleton, results in a combination of tension and compression (see Fig. 80-7). Typically, tensile stresses act on one side of the bone and compressive stresses act on the other side. Failure occurs along the plane of maximal shear stress, resulting in a butterfly fragment along the plane of the maximal shear-stress (Fig. 80-7).

During torsion, equal and opposite loads are applied at opposite ends of the structure, resulting in twisting forces that cause the bone to rotate. The bone fails along the plane of maximal shear stress, which is usually oblique to the axis of the bone (Fig. 80-7). Torsional fractures are common in the appendicular skeleton, particularly in the distal radius and ulna, and can result in a spiral or transverse fracture configuration.

Shear loading, which involves forces that act parallel to the plane of the bone, results in shear stresses and strains. The bone fails along the plane of maximal shear stress, which is usually perpendicular to the direction of the shear force. Shear fractures are common in the appendicular skeleton, particularly in the distal radius and ulna, and can result in a spiral or transverse fracture configuration.

Combined loading, which involves a combination of two or more loading modes, results in a complex response that depends on the specific combination of loads. The bone fails along the plane of maximal shear stress, which is usually intermediate between the planes of the individual loading modes. Combined loading is common in the appendicular skeleton, particularly in the distal radius and ulna, and can result in a spiral or transverse fracture configuration.

Figure 80-6. The various loading conditions that bone is subjected to during normal daily activities. From top to bottom and left to right: no load, tension, compression, bending, shear, torsion, and compression and torsion.

Figure 80-7. Long bone fracture configurations associated with the typical forces that result in fracture. A, In pure tension, the bone fails transversely. B, In compression, the bone fails obliquely along the maximal shear plane. C, In torsion, the fracture initiates in shear along the surface of the bone and then propagates in tension in a spiral manner. D, In pure bending, the bone initially fails in tension (small arrows), and the fracture propagates toward the compressive surface, resulting in a small butterfly fragment. E, In combined compression and bending, the bone initially fails in tension (small arrows), and the fracture propagates toward the compression surface, resulting in a large butterfly fragment along the maximal shear plane.
opposite cortex. The neutral axis is defined as the plane within the bone that is not subjected to tension or compression. The farther from the neutral axis, the greater the magnitude of the tensile and compressive stresses. Both clinically and experimentally, bending can be three-point or four-point bending (Fig. 80-8). Three-point bending occurs when three forces act on a bone to produce two equal maximal bending moments. The bending stress is concentrated at the point of load application, and fractures typically occur at this point. A typical three-point bending fracture in a horse occurs at the top of a cast or when the horse steps in a hole. Since adult bone is weakest in tension, failure begins on the tensile surface of the bone and subsequently progresses to the surface along the maximal tension plane until shear forces acting on 45-degree planes become sufficiently high to cause a butterfly fracture at the compressive surface of the bone.

Four-point bending is caused by two force couples or four forces (two central and two peripheral) acting on a structure to produce two equal moments (see Fig. 80-8). The region between the two central application points is subjected to a uniform bending moment, and the bone fractures through the weakest portion of the bone in this central region. Four-point bending rarely results in a fracture clinically, but it is often used when experimentally determining the biomechanical properties of bone.

Torsion occurs when a load is applied to a structure and results in twisting around an axis, causing torque to be produced within the structure (see Fig. 80-7, C). When a bone is subjected to torsion, shear stresses are distributed over the entire structure. As with bending loads, the magnitude of these stresses is proportional to their distance from the neutral axis (usually the central axis of rotation). Therefore, the periosteal surface of bone is typically subjected to the highest shear stresses when a bone is loaded in torsion. Maximal tensile and compressive stresses always act on a plane at 45 degrees relative to the maximal shear-stress plane as a result of the large shear stresses that occur on the surface of the bone. A bone loaded in torsion first fails in shear along its outer surface with the formation of cracks parallel to the long axis of the cortex. Subsequent cracks then form along the plane of maximal tensile stress, causing a spiral fracture to occur.

The most common loading pattern that occurs during normal daily activities is combined loading. Bones are regularly subjected to complex loads in multiple directions that occur simultaneously. This results in varying strains in different orientations depending on the surface of the bone evaluated, the geometry of the bone, and the portion of the bone being examined.

An extremely important property of bone is its rate dependency. Since bone is viscoelastic, the faster the bone is loaded, the greater are its stiffness, strength, and energy absorption during loading. Therefore, if a bone is rapidly loaded and then fails, this greater energy absorption is released during fracture, causing greater comminution as well as greater soft tissue injury. At lower loading rates, bone is less stiff, fails at a lower load, and stores less energy prior to failure, typically resulting in simple fractures with little comminution and less displacement of the bone fragments.

Fractures can occur as a result of a single incident or secondary to repeated loading cycles. Bones that fail secondary to repeated cyclic loading are typically viewed as failing secondary to a fatigue fracture (Fig. 80-9). Under cyclic loads, the susceptibility of bone to fracture is related to its crystal structure and collagen orientation reflected by its viscoelastic properties. Cortical bone is particularly
vulnerable to both tensile and compressive cyclic stresses. Fatigue load under certain strain rates can cause progressive microdamage accumulation in cortical bone (Fig. 80-10). If this process continues, the bone may eventually fail through coalescences and propagation of these cracks. Although cortical bone is relatively brittle and has poor fatigue resistance in vitro, it is a living tissue that can remodel and repair during and after loading, as occurs in shin splints in horses. Periosteal new bone formation near microcrack formation can arrest crack propagation by reducing the stresses encountered at the tip of the crack. In a fatigue test, the endurance limit of a bone is the stress level under which no fractures can develop regardless of the number of loading cycles applied. For this repair process to be effective following fatigue-induced microcracks, relatively low loads must be present and be maintained to allow sufficient time for the repair process to occur.

**BIOLOGIC REACTION AND HEALING OF BONE**

To successfully treat fractures, knowledge of bone biology and of the causes, management strategies, and healing of fractures is essential. Fracture healing typically results in the return of the injured bone to its original form and function and involves a number of significant processes that can be regarded as temporary reversion to the embryonic state. Skin, muscle, and tendon tissue, unlike bone, are unable to fully regenerate after injury, but rather heal with a permanent scar.

Fracture healing involves a series of overlapping processes that occur in the majority of fractures. These stages are typically referred to as the inflammatory phase, the reparative phase, and the remodeling phase. The inflammatory phase is a critical prerequisite for the reparative phase of fracture healing and usually occurs during the first 2 to 3 weeks after injury. If impairment of the inflammatory phase occurs, fracture healing is compromised. During the inflammatory phase, several cellular mechanisms responsible for repair of the fracture and protection of the healing tissue from infection are activated. Various chemical mediators cause vasodilation, migration of leukocytes, and chemotaxis. Platelets contribute cytokines that assist in mesenchymal cell proliferation and angiogenesis. After migration to the injured site, granulocytes ingest and destroy bacteria but do not contribute to repair. Macrophages and to a smaller extent lymphocytes also aide in the destruction of bacteria and stimulate repair by releasing both cell growth factors and angiogenic factors.

The reparative phase follows and overlaps with the inflammatory phase. During the reparative phase of fracture healing, the bone is highly susceptible to mechanical factors such as interfragmentary motion between fracture fragments. The reparative phase can take between 2 and 12 months to be completed. Without immobilization, the natural course of fracture healing begins with interfragmentary stabilization by both periosteal and endosteal callus formation. This process restores continuity of the bone and union occurs by endochondral and intramembranous ossification (Fig. 80-11).

The remodeling phase occurs during and after the reparative phase. The vascular and necrotic regions of bone are replaced through osteonal remodeling (Fig. 80-12). Alignment of the fragments can be corrected to a certain extent by remodeling of the healed bone. During loading, convex surfaces carry a positive charge and attract osteoclasts, whereas concave surfaces carry a negative charge and attract osteoblasts. Therefore, bone is laid down on concave surfaces and removed from convex surfaces, helping to straighten a malaligned bone. Over 40 years ago, it was discovered that rigid compression plating of a fracture inhibited callus formation, allowing bone ends to unite via haversian remodeling.

**Figure 80-10.** Grayscale composite Z-stacked confocal photomicrograph of a bone 7 days after fatigue loading bulk-stained with basic fuchsin. The osteocyte syncytium in this region has lost its normal canalicular network and has become devitalized (see Fig. 80-2). A prominent microcrack is clearly visible in the cortical bone.

**Figure 80-11.** The typical soft tissue response associated with normal fracture healing. a, external soft tissue reaction; b, periosteal reaction; c, cortical reaction; d, bone marrow reaction. (Adapted with permission from Markel MD: Fracture healing and its noninvasive assessment. In Nixon AJ, editor: Equine Fracture Repair, Philadelphia, 1995, WB Saunders.)
replaced by new bone.10 Between the fracture fragments, which is subsequently either fibrous tissue or fibrocartilage is formed initially endosteal callus formation, is considered secondary because fracture healing, which requires healing by periosteal and healing and secondary (or indirect) fracture healing. Indirect two distinct patterns, including primary (or direct) bone united (but with porous bone that is in the process of being remodeled).

Eight weeks after fracture, with porous woven bone C, Twelve weeks after fracture healing, with the cortex filling the gap.

In contact areas (contact healing) and noncontact areas (gap healing).15 Fracture healing was subsequently divided into two distinct patterns, including primary (or direct) bone healing and secondary (or indirect) fracture healing. Indirect fracture healing, which requires healing by periosteal and endosteal callus formation, is considered secondary because either fibrous tissue or fibrocartilage is formed initially between the fracture fragments, which is subsequently replaced by new bone.16

The ultimate goal of fracture healing is to reconstruct the original cortical bone (see Fig. 80-12). The cortical ends of the fracture site become avascular and necrotic immediately after the fracture. Fortunately, this vascular compromise does not prevent the avascular ends from serving important biomechanical roles as supportive elements for a fracture fixation device. Haversian remodeling of the unifying fracture serves two principal functions—the revascularization of necrotic bone at the fracture site and the reconstitution of the interfragmentary gaps. There are three specific requirements for haversian remodeling to occur across a fracture site. These include adequate reduction, rigid fixation, and sufficient blood supply. Haversian remodeling of the fracture typically begins in the second to third month after fracture healing. It is unknown exactly what factors initiate the dramatic increase in secondary osteon formation, which occurs during fracture healing, but it has been postulated that the activation of haversian remodeling is related to tissue damage at the fracture site.10

Progression of secondary osteons from one fracture fragment to another does not require intimate contact of fracture fragments. Even with perfect reduction and rigid internal fixation, there are incongruencies at the fracture site that result in small gaps between areas of contact. These gaps are typically filled within weeks after the fracture occurs by direct lamellar or woven new bone. Secondary osteons use this gap tissue as a scaffold to grow from one fragment to another. Although growth and progression of these secondary osteons are critical for final union, the growth typically results in a transitory reduction of cortical bone density because of increased porosity.16

As highlighted, fracture healing can follow any number of pathways to the final stage of union. The choice of which path to follow depends on many factors, including the surgeon’s expertise and experience. There is certainly not one fixation technique that is superior to all others for all fractures. Many clinical factors, such as the animal’s age, prospective use, value, and attitude, and fracture configuration play important roles in the selection of a fixation method. Fortunately, fracture healing appears to have a high level of tolerance and adaptability to even the most adverse conditions.

**Figure 80-12.** Light microscopic images of a 5-µm undecalcified specimen of a fracture gap (Goldner stain, ×20). A, Two weeks after fracture healing, the gap has filled with undifferentiated mesenchymal tissue. B, Four weeks after fracture healing, with islands of cartilage (c) and bone (b). C, Eight weeks after fracture, with porous woven bone filling the gap. D, Twelve weeks after fracture healing, with the cortex united (but with porous bone that is in the process of being remodeled).

**EVALUATION OF HEALING FOR CLINICAL JUDGMENTS**

Determination of effective osseous fracture union can be a diagnostic challenge. Clinical assessment requires comprehensive consideration of numerous factors including initial trauma, healing period length, fracture site pain, palpable callus, lameness, and stability on manual examination. For bones underlying deep tissue, clinical assessment is often qualitative.

Radiographic evaluation is the standard modality by which fracture healing is assessed. Secondary bone healing is the most common mechanism of equine fracture healing, and radiographic changes coincide with the three phases of fracture repair described earlier. Up to a week after the initial trauma, sharp fracture margins are typically visible.17 Once the locally mediated inflammation of the inflammatory phase is established, necrotic bone is removed by osteoclasts and phagocytes. During this period, approximately 2 to 3 weeks after fracture, the fracture gap appears to widen and its margins become indistinct.

During the ensuing reparative phase, periosteal, endosteal, and intercortical calluses become evident, although they vary in radiographic visibility depending on the degree of mineralization, which in turn depends on local blood supply and tissue oxygenation. Initial callus formation occurs within 5 days after trauma, but bony callus requires adequate mineralization to be radiographically evident. As healing progresses, fracture lines disappear and the external callus increases in opacity relative to adjacent bone. The size and shape of an external callus is significantly influenced by
motion at the fracture site, with greater motion resulting in a larger callus. In the remodeling phase, the woven and cancellous bone of the callus transition to lamellar bone. As remodeling progresses, the callus is revised to the original conformation of the bone. Traditionally, bony unions are characterized radiographically by a bony callus, obliteration of the fracture line by bony trabeculae, and cortical bone bridging the fracture gap.18

Development of methods to improve evaluation of equine bone healing is an area of ongoing research. Nuclear scintigraphy is one modality that has been used to evaluate equine fracture healing.19-21 It is advantageous in that it provides a clear assessment of fracture vascularity for prognostic purposes. Both computed tomography and nuclear scintigraphy have been used to detect and assess equine fractures, although computed tomography has not been applied extensively to assess fracture healing.19,22-23 Dual x-ray absorptiometry (DEXA), magnetic resonance imaging (MRI), and ultrasonography are gaining in popularity for evaluating fracture healing in human and small animal patients, but they are not routinely applied to the horse.20-28 Methods for enhancement of traditional radiography to assess the degree of equine fracture healing will most likely become more common with development of equine-specific equipment and methodology.

COMPLICATIONS
Complications of equine fracture healing include infection, fixation failure, delay or failure of bony union, and stress-induced laminitis. These are broad generalizations that represent some common problems associated with fracture repair. Each fracture and patient is unique and subject to individual variation and associated complications. Complications should be specifically addressed as they arise.

Perioperative antibiotic administration and improved surgical techniques and equipment have significantly reduced the incidence of nosocomial equine orthopedic infections, but severe soft tissue damage often associated with the initial injury can result in exposed bone and severe contamination. In spite of appropriate surgical débridement and antibiotic administration, compromised blood supply, swelling, edema, and necrotic tissues provide an ideal environment for bacterial proliferation. Local infection can easily proceed through the cortex, marrow, and articulations of bones involved. Treatment of osteomyelitis after fracture stabilization requires individualized assessment and therapy. Additional information on bone infections can be found in Chapter 88.

Many factors are associated with delay or failure of fracture union, including but not limited to, infection, inadequate reduction, inadequate immobilization, and soft tissue disruption. Delayed union refers to the situation in which healing is not complete within an adequate time interval for fracture union. Healing progresses, but at a slower rate than normal. Typically, long bone fractures are expected to heal within approximately 4 months in adult horses and 3 months in foals. Nonunion occurs when fracture repair ceases prior to restoration of the bony structure. Three types of nonunion have been identified—vascular, avascular, and infected nonunions. Treatment depends on the specific condition present.

Stress-induced laminitis is a complicating factor in many fracture repairs. The basic cause of the condition is related to continued severe lameness after fracture fixation. The primary goal of any form of fracture stabilization is return to comfortable weightbearing on the affected limb as quickly as possible. In spite of appropriate, stable reduction and analgesic administration, continued pain in some fractured limbs results in increased weightbearing on the contralateral limb. Stress-induced laminitis generally does not have a metabolic component. It can result in rotation and even sinking of the distal phalanx as the germinal layers separate from the horny tissues in the hoof.

Fixation failure, either of external coaptation or of the surgical implant, can occur in the horse for any number of reasons, not the least of which are the forces inherent to the equine limb. External coaptation is not used routinely for fracture stabilization but usually for protection of surgical reduction and stabilization in the postoperative period. Transfixation casts are used on occasion. Cast complications, pin breakage, fracture through pin holes, and pin-track infections are problems associated with such stabilization. Surgical implant complications are often associated with the strength of the fixation construct relative to the mechanical demands placed on it. Catastrophic fracture construct failure may occur when it is exposed to forces that exceed the implant strength, such as during recovery, or when the rate of bone healing is slower than the implant fatigue life. Implant loosening as a result of localized implant or bony failure can result in an unstable fracture and delayed healing. Although no amount of caution can prevent all fixation-associated problems, appropriate preoperative planning, fracture stabilization, and postoperative care improve chances of success considerably.

DISTRACTION OSTEOGENESIS
Distraction osteogenesis is the formation of new bone by controlled separation of stabilized bone ends on each side of a corticotomy or osteotomy.29,30 To achieve bone formation, there must be adequate fixator stability, adequate periosteal and medullary blood supply, minimal soft tissue disruption, and physiologic use of the bone.31,32 Bone formation also depends on the appropriate distraction rate and rhythm, the length of distraction, and the number of distraction increments every 24 hours. New bone, referred to as regenerate bone, forms according to a general principle called the tension-stress effect.33 Specifically, early callus tissue subjected to slow steady traction is metabolically stimulated to differentiate and proliferate in the distraction gap.

The process of distraction osteogenesis is divided into three periods—latency, activation, and consolidation.29,30 The latency period is the time between bone transection and the initiation of distraction, which is postulated to enhance cellular and vascular responses and improve osteogenesis. The activation period is characterized by bony in-growth as distraction is applied. Within 3 to 7 days after bone transection, osteoblast or osteoclast progenitor cells on the bone surface differentiate according to the mechanical and biologic environment and begin to proliferate. Osteoid is laid down in parallel columns extending centrally from each bone surface.33 Lamellar bone typically develops within the
columns, but fibrous tissue formation may occur if the fracture site is sufficiently unstable. The distraction device remains in place to serve as rigid skeletal fixation until maturation of new bone is achieved during the consolidation period. Metaphyseal cancellous bone does not heal the same way cortical bone does, because trabecular bone is inherently more stable.34 Periosteal callus formation does not occur unless there is significant instability. Instead, osteoblasts deposit new bone on trabeculae, and the fracture gap fills with woven bone, bridging the trabeculae prior to cortical union. As with any fracture, individualized distraction osteogenesis must be based on patient age and health, the bone involved, the osteotomy type and location, and the degree of soft tissue trauma.

Distraction osteogenesis has limited potential for equine application. Circular external fixator stress is usually inadequate for stabilization of equine long bones, with the possible exception of small foals. Successful correction of a deviated nasal septum and premaxilla in a yearling filly has been accomplished with distraction osteogenesis, and distraction osteogenesis may be useful for mandibular elongation to treat equine brachygnathism in both juvenile and adult patients.35,36 With careful case selection and appropriate external or internal fixator construction, it is possible that distraction osteogenesis may be a useful treatment in certain equine patients.

STIMULATION OF BONE HEALING

Enhancement of fracture healing for rapid restoration of skeletal function could greatly benefit the equine patient. Both biologic and mechanical methods to accelerate the process of bone repair have been evaluated in the horse. Local biologic methods for enhancement of fracture healing most frequently include the use of autogenous cancellous and cortical bone grafts, though both autogenous and allogeneic demineralized bone matrix and allogeneic bone have also been used to facilitate bone repair.21,37,38 Grafts have varying capacities to provide cells for active bone formation (osteoinduction), to induce bone formation by host cells (osteoinduction), and to provide a substrate for bone formation (osteocconducton). Successful graft incorporation requires an appropriate match between the biologic graft activity, the surrounding host tissues, and the mechanical environment (see Chapter 82).

A number of growth-promoting substances involved in regulation of fracture repair have been identified. They are generally categorized into two groups: growth factors and immunomodulatory cytokines. These substances have been investigated for promotion of equine articular cartilage repair, but to date, augmentation of equine fracture repair by exogenous administration of growth-promoting substances is not well investigated (see Chapter 79).39,40

One of the most highly investigated mechanical techniques to stimulate fracture healing in the horse is the application of electric and electromagnetic fields.41-45 The premise for such treatment is based on Wolff’s law: living bone adapts its structure in response to mechanical stress by producing electric potentials that optimize bone growth. There is a large body of evidence that metabolic activity and mechanical deformation in living bone generate steady direct current and time-varying electric fields, respectively.46 Numerous basic research and clinical investigations surrounding stimulation of bone repair with energy application have been conducted across species. There are anecdotal reports of treatment success in the horse, but clinical efficacy has yet to be clearly established.41,47

CHAPTER 81
Principles of Fracture Treatment
Jörg A. Auer

Fractures are diagnosed in practically every bone of the horse and encountered at all ages. Fractures vary in clinical presentation and significance, ranging from exercise-induced fractures causing only relatively minor lameness, such as chip fractures of the carpus, to fractures causing a nonweightbearing lameness, such as a transverse failure of the third metacarpal bone (MCIII). The management of intra-articular chip fractures and osteochondrosis lesions will be discussed in Chapters 84 and 91, respectively. In this chapter, the principles of fracture treatment, nonsurgical and surgical, are presented.

Fracture treatment in the horse follows the same basic guidelines developed for humans and small animals. Many techniques can be derived from them, but some principles in the treatment of equine long bone fractures are unique. These differences are discussed in detail, with emphasis given to surgical fracture treatment, including internal fixation and external coaptation.

NONSURGICAL MANAGEMENT
Some fractures heal sufficiently with nonsurgical management to allow the animal to return to an athletic career. Nonsurgical management techniques include stall rest and external coaptation.

CHAPTER 81

Principles of Fracture Treatment
Jörg A. Auer

Fractures are diagnosed in practically every bone of the horse and encountered at all ages. Fractures vary in clinical presentation and significance, ranging from exercise-induced fractures causing only relatively minor lameness, such as chip fractures of the carpus, to fractures causing non-weightbearing lameness, such as a transverse failure of the third metacarpal bone (MCIII). The management of intra-articular chip fractures and osteochondrosis lesions will be discussed in Chapters 84 and 91, respectively. In this chapter, the principles of fracture treatment, nonsurgical and surgical, are presented.

Fracture treatment in the horse follows the same basic guidelines developed for humans and small animals. Many techniques can be derived from them, but some principles in the treatment of equine long bone fractures are unique. These differences are discussed in detail, with emphasis given to surgical fracture treatment, including internal fixation and external coaptation.

NONSURGICAL MANAGEMENT

Some fractures heal sufficiently with nonsurgical management to allow the animal to return to an athletic career. Nonsurgical management techniques include stall rest and external coaptation.
Stall Rest
Frequently, horses are admitted in a “fracture-lame” state without a visible or palpable fracture. According to the anamnesis, these patients were found on pasture with the non-weightbearing lameness, or they did not return to the stable in the evening with the other horses. The physical examination may reveal a small wound over a vestigial metacarpal or metatarsal bone, the radius, or the tibia. In the case of splint bone fracture, radiography may reveal a fracture or even multiple fractures. In selected cases, these fractures are amenable to nonsurgical management with a bandage alone. Additional information on the treatment of these fractures is found in Chapter 95.

Other fractures amenable to management by stall rest include fractures of the deltoid tubercle, nonarticular patellar fractures, and fractures of the scapular spine. However, for the vast majority of fractures, nonsurgical management is not the treatment of choice and should not be advocated.

External Coaptation
For a detailed description of the indications and applications of external coaptation devices, such as fiberglass casts and splints, please review Chapter 18. In this chapter, external coaptation is discussed as it pertains to fracture treatment.

Splints
The indications for limb splints as a sole means of fracture treatment are limited. More commonly, they are used as a form of emergency fixation [see Chapter 78]. This type of external coaptation may be employed in fissure fractures of the diaphysis of the radius and tibia, or as adjunct treatment to internal fixation of a fracture, either during the immediate postoperative period or as an intermediary step after removal of a cast.

In acute fissure fractures of the radius and tibia, radiography may not show a fracture. Affected animals are usually reluctant to bear any weight on the limb. Initial management should include not only the application of a splint bandage but prevention of the animal from lying down. It is frequently during the process of lying down or getting up that these fissure fractures evolve into complete fractures. Tying the horse with a short rope and providing a filled hay net to allow them to eat is an effective management method. Nonsteroidal anti-inflammatory agents are indicated to provide some comfort. However, the dosages should not be so high that they abolish the lameness completely. A complementary or independent management option involves the application of sling or rescue net (Fig. 81-1). Usually, the animals tolerate these slings very well. They allow the patient to rest their intact limbs for some time by lowering their abdomen into the sling. It is important that the sling be installed such that the body has to be lowered only a few centimeters to allow it to rest in the sling. If the body has to be lowered too much, complete fractures of the bone may still occur.

If initially no fracture can be found on radiography, additional images should be taken a few days later. Usually, at this point, fractures may be seen radiographically (Fig. 81-2). Depending on the configuration of the fissure fracture and the width of the fracture gap, the management may be modified. When the fissure lines are small with a barely visible gap, no bandages are needed, but the animal is maintained in the sling for 2 to 3 weeks. If the fracture line is long and associated with a significant gap, the splint bandage should be maintained.

Splint bandages should be changed every 3 to 4 days, and in hot and humid climates they should be changed more frequently. Caution should be used during the process because weightbearing on the limb without the splint or bandage could have deleterious effects on fracture healing.

Figure 81-1. An adult horse suffering from a fissure fracture of the tibia, supported by a rescue net. The net, which is applied relatively snugly to allow the horse to apply some weight to it, is tolerated very well.

Figure 81-2. Craniocaudal and lateromedial radiographic views of a fissure fracture in the proximal metaphysis of the tibia of an adult horse.
Casts
External coaptation using fiberglass cast material as the primary treatment technique of a fracture may initially be considered as a conservative, less expensive type of treatment. However, the frequent cast changes usually necessitated by soft tissue problems must usually be carried out under general anesthesia. The costs of several anesthetic events, cast materials, and professional fees add up rapidly and may soon exceed the costs of a state-of-the-art internal fixation performed on admission. Additionally, the advantages of early return to function, achieved through internal fixation, are lost. Cast materials selected for fracture treatment should be of the fiberglass type, because this material allows the skin and the limb underneath the cast to breathe. Also, it is lighter in weight, so the animal is more comfortable.

Casts should be palpated daily and evaluated for hot areas. Any odor from the cast should be investigated, and weightbearing on the limb should be evaluated. Sudden changes in weightbearing patterns, edema above the proximal cast end, and a foul odor or wet spots on the cast are signals of skin damage and possible necrosis underneath the cast. The same is true when hot areas develop in the fetlock region or at the dorsal aspect of the cast in the region of the hoof wall constrict. After the cast is removed and the limb is loaded once again, the foot expands, which causes pain for several days.

If a foot is maintained under a cast while a fracture in the limb is allowed to heal, it is prevented from expanding during weightbearing and the structures underneath the hoof wall constrict. After the cast is removed and the limb is loaded once again, the foot expands, which causes pain for several days.

Flexing of the joints after a prolonged fixation in one position causes pain and an initial unwillingness to bear weight. This, however, is overcome after a few days in most cases and can be facilitated with anti-inflammatory drugs.

Complications
Nonsurgical management of fractures is associated with various complications (see Chapter 18). When internal fixation is not applied, the fracture fragments are not stable. The resulting callus formation often impinges on soft tissue structures or tendons and may prevent future athletic use. However, bone remodeling after fracture healing may reduce such a callus, eliminating impingement on the soft tissue structures.

Skin trauma from casts and splints can be severe enough to endanger the outcome of fracture healing. It is important that the skin remain dry and healthy. Development of cast sores should be monitored. If they do develop, casts must be changed frequently and padded so that the pressure on the skin is redistributed.

If infection develops underneath the cast, swelling causes increased pressure within the tissues. Because the skin cannot expand beyond the inner limitations of the cast, a compartment syndrome develops, resulting in tissue necrosis. Additionally, drainage from the limb accumulates within the cast, and the skin will be damaged by enzymes. Hosing down the cast with copious amounts of water on a daily basis prolongs its usefulness and postpones a change, but an infected limb should be maintained under a cast only if no alternative exists.

During the time that the limb is maintained in the cast, the joints are unable to move and the articular cartilage is poorly nourished. This results in loss of proteoglycans and subsequent degeneration of the cartilage. Additionally, the soft tissue structures surrounding the joint are not flexed and stretched, which causes them to become weak and inelastic. When prolonged external coaptation is used, these pathologic changes are exacerbated and are referred to as "cast disease."

Surgical Management
Equine bone reacts to trauma and fracture with active new bone formation and subsequent remodeling. Many osteons are mobilized to facilitate remodeling of the cortex. However, fracture healing in the horse occurs at a slower pace than in most other animals, especially ruminants, small animals, and humans. Therefore, any adjunct treatment that benefits bone healing is advantageous.

External Fixation
External fixation using intraosseous or transosseous pins and clamps is common in humans and small animals but less so in the horse. This type of fixation is employed frequently as emergency treatment in open or in severely comminuted fractures when anatomic reduction, reconstruction, and internal fixation of the fracture are not possible. External fixation techniques can be applied using three types of constructs: transfixation-pin casts, an external fixator, or an external skeletal fixation device.

Transfixation-Pin Casting
Nemeth and Back popularized transfixation-pin casting among equine specialists. This efficient and relatively easily applied treatment method is indicated for comminuted fractures of the phalanges, the distal MCIII/MTIII, and breakdown injuries of the metacarpophalangeal joint. A retrospective study involving more than 50 horses and ponies treated by means of transfixation-pin casting showed that comminuted fractures had better results (86% healed) than simple fractures (23% healed). It is assumed that the micro-motion between the fragments after fixation was distributed between more fragments in the comminuted fracture and therefore was decreased compared with simple transverse fracture, where distribution was not possible.
Under aseptic conditions two to three cross-pins of 4 to 6 mm in diameter are introduced in the metaphyseal region of the bone. The use of positive-profile pins (IMEX Veterinary Inc, Longview, Tex) is preferred.9 A 30-degree divergence of the pins in the frontal plane results in a stronger fixation and lower risk for postoperative fracture.10,11 The pins should be separated by 2 to 4 cm. A stab incision is made down to the bone and, using tissue protection, the predetermined-size hole is prepared. An effective method of heat control is to initially drill a smaller hole, followed by stepwise enlargement through larger drill bits. Production of heat is associated with bone necrosis around the pin and its subsequent loosening.

A pin with a diameter that is 0.1 mm larger than the prepared hole (radial preload of 0.1 mm) provides the best pin holding strength with the least weakening of the bone surrounding the implant.1 If positive-threaded pins are used, appropriate threads have to be cut in the pre-drilled hole prior to pin insertion. Newer pin generations are equipped with a self-tapping device at the beginning of the threaded part. Care has to be taken to engage the threaded pin portion with both cortices. Protruding portions of the pins are cut off at a length of 3 to 5 cm from the limb, which allows their incorporation into the cast.

After applying a double layer of stockinet, followed by a double layer of resin-impregnated foam padding (3M Corporation, St. Paul, Minn), a 5-mm layer of fiberglass cast is applied as described in Chapter 18. The ends of the pins can be covered by hoof acrylic and incorporated in an additional layer of fiberglass cast tape (Fig. 81-3). An alternative approach involves the application of dowels over the pin ends, fastened with fixation screws on the pins, just adjacent to the layer of casting tape. These dowels are subsequently covered by an additional solid layer of cast material. These two methods prevent migration of the pins after loosening, because they are fixed within the cast. A recent in vitro study revealed that the fixation of the pin within the cast plays a minor role.12 The fiberglass cast material appears to be the major determinant of axial stability. However, because it was an in vitro study, the long-term effect of such a fixation could not be evaluated. Therefore, an additional fixation device, as described earlier, may still have some merit.

The incorporation of horizontal pins in a u-bar fastened around the distal limb has been advocated.9 This technique was thought to allow some weightbearing, but this has been disproven.13 A combination of transfixation-pin casting and strategic lag screw placement across major fracture lines to ensure anatomic reduction of intra-articular fractures may speed up fracture healing.

Centrally threaded, positive-profile transfixation pins have greater resistance to axial extraction in the diaphysis than in the metaphysis of equine MCIII bone in vitro.14 Again, this observation resulted from an in vitro study and may lead to the conclusion that it is advantageous to introduce the pins into the diaphyseal region of the long bone. However, the author’s experience is that diaphyseal pins lead to more complications, which include ring sequestrum formation and subsequent pathologic fractures.

Advantages of transfixation-pin casting include no load on the fracture site and minimal distraction and movement between the fragments. Also, the tissues are spared additional trauma and further disruption of the blood supply. All the disadvantages of external coaptation, such as the development of cast disease, osteoporosis, contracted feet, and tendon laxity, apply to this type of treatment. Pin tract infection with ring sequestrum formation can occur and is preceded by a sudden onset of lameness. This usually occurs in heavy horses (greater than 500 kg of bodyweight) and warrants immediate removal of the proximal transfixation pin. Another pin can be inserted at a different location to prolong unloading of the fracture, or, alternatively, the limb can be placed in a new cast without the proximal-most pin. A new pin can be expected to form a similar sequestrum within the next 2 weeks, and the procedure can be repeated. If three pins are inserted initially, transfixation may be maintained for 6 to 8 weeks, before simple casting is applied. At that time, a full-limb cast is applied to prevent rotation of the MCIII/MTHIII. (Rotation can occur in a half-limb cast and may lead to a fracture across a pin tract.)

External Fixator

Application of an external fixator allows immediate, although subnormal, weightbearing on the limb. The Steinmann pins and Schanz screws used with this fixation device create minimal additional trauma to the injured soft tissue. Because in most cases no external coaptation is used, there is easy access to an open wound, which facilitates débridement and management. Application of an external
fixator also allows additional correction and fracture alignment after the initial operation, whereas a fracture treated with internal fixation can be adjusted only through an additional surgery. However, this technique has not been very successful in equine patients.

An external fixator utilizes transversely inserted (cross) Steinmann pins or Schanz screws (Steinmann pins with a threaded end) proximal and distal to the fracture site. These pins are firmly connected to external rods through special clamps, which may be applied in many configurations. An in vitro study showed that the best results are achieved with an elaborate three-dimensional design, including three Steinmann pins proximal and distal to the osteotomy, inserted at different angles in the frontal plane and obliquely from proximal to distal, and connected to four external rods. Such a configuration is expensive and very heavy and therefore not practical.

To improve the bone-holding properties of Schanz screws, a new design has been developed by the AO/ASIF group. It has the features of the ideal pin with a 0.1-mm greater diameter than the hole drilled for it (larger radial preloads result in microfractures and deformation of the bone surrounding the pin, with subsequent loosening). The Seldrill Schanz screw is manufactured of pure titanium and stainless steel and has a self-drilling, self-tapping tip. This implant is inserted through a stab incision without predrilling the bone or pretapping the hole, even in hard equine bone. The Seldrill Schanz screw contains a relatively thick core and thin threads and includes a portion with a built-in radial preload of 0.1 mm, immediately adjacent to the self-drilling, self-tapping tip. Because the sharp tip should not exit the opposite cortex, this implant is to be used in half splints (type I), where the external tube or rod is located only on one side of the bone. Additionally, this device can be used in three-dimensional (type III) configurations, where a half splint is connected to a full, bilateral splint (type II), which uses nonthreaded pins.

A modification of an external fixator, the Pinless external fixator, is available for selected fractures in large animals. This device is manufactured in three sizes and configurations of clamps, which are applied over a bone without completely penetrating the cortex (Fig. 81-4). The clamps are fastened through a connection rod and clamps to an external fixator tube or carbon rod. This device is not rigid enough to support weightbearing of a large animal with a fractured limb, but it is effective in stabilizing mandible fractures in cattle and horses (see Chapter 103) and fractures of the tail in the horse (see Chapter 53). In vivo studies show that the clamping force is maintained over several weeks while inducing only minor bony changes where the clamps contact the bone. Animals tolerate the device well. The advantage of this type of external fixator is the minimal damage to bone and tooth roots.

External Skeletal Fixation Device

The external skeletal fixation device (ESFD) was developed for horses with severely comminuted fractures of the phalanges, fractures of the distal MCIII/MTIII, and "breakdown injuries" of the metacarpophalangeal joint: The ESFD uses two to three transfixation pins in the intact bone proximal to the fracture, and sidebars and a base plate. Weightbearing forces are transmitted via the pins and sidebars around the fracture to the ground, allowing the animal to immediately bear full weight without loading the fracture. The original report described the device and 15 cases, only four of which survived long term. Through a meticulous study of the design, an effective ESFD transfixation system has been developed and is commercially available. Early complications included fractures through the pin tract while the device was worn, or during recovery after implant removal. These complications were almost completely abolished with the latest generation ESFD. Removal of the device on the sedated, standing animal eliminates some problems
encountered after device removal, but the risk of fracture while wearing the device continues.\(^\text{21}\)  
Up to 90\% of the stresses generated at the bone-pin interface contribute directly to pin bending, resulting in uneven stress distribution, with peak stresses concentrated at the outer bone cortex.\(^\text{22}\) The new design has been modified to minimize transcortical pin bending with weightbearing. It enhances overall fixation stiffness and minimizes complications at the bone-pin interface. Large-diameter, tapered sleeves are applied over the transfixation pins (biaxially loaded in tension and shear) and are incorporated in a stronger, lighter frame\(^\text{23}\) (Fig. 81-5). In vitro tests applying cyclic loading show that significant increases in stiffness, reduced bending, and increases in load-to-failure-of-bone could be achieved with the new sleeved-pin design.\(^\text{23}\) Since bone failure occurs at a finite strain level, it appeared that the larger loads to failure were indicative of lower strains in the bone at the working stress level.

**Aftercare**

Application of an external fixator or ESFD allows easy wound management of open fractures. Débridement should be performed under aseptic conditions, and every measure must be taken to prevent additional contamination. Broad-spectrum antibiotic coverage is indicated in any horse treated with external fixation during the entire time the device is in place. The skin around the cross pins should be cleaned daily with alcohol-soaked swabs and dried before reapplication of the bandage. Internal fixation of the fracture may be considered once the infection has subsided and healthy granulation tissue has formed. At that time, the external fixation device is removed. Any sudden changes in weightbearing patterns are indications for close scrutiny of the fracture and the fixation device. Radiographs should be taken at the onset of any complication and repeated in routine fashion at 2- to 4-week intervals without complications. Once fracture healing has occurred, the device is removed. The abrupt change in stability caused by removal of the external fixator can be minimized through partial destabilization of the device. This is best achieved by moving the vertical connecting bars farther away from the limb. An alternative approach involves the strategic removal of one or two pins at 2- to 3-week intervals. After a few weeks in this configuration, the device is removed.

**Complications**

Loosening of the pins, infected pin tracts, and fracture through a pin hole are the main complications of external fixation in horses.\(^\text{13}\) Loosening of cross pins is the most frequent complication of external fixation.\(^\text{24}\) Weightbearing on the affected limb causes osteolysis around the pins, followed by infection of the pin tract and subsequent loosening.\(^\text{24}\) Once a pin loosens, pain develops. A loose pin should be removed immediately, because it no longer serves a useful function, and infection around it will not subside as long as the pin remains in situ. Curetting and flushing of the tract facilitates cessation of draining within a few days. If drainage persists, the skin should be reopened, followed by an additional curettage of the pin tract. Removal of a loose pin destabilizes the fixation. Depending on the degree of fracture healing, it is important that pins be removed one at a time. Premature removal of the implants results in total instability.

Removal of a loose transfixation pin is performed on the standing, sedated horse. If external coaptation was used, cast material immediately adjacent to the pin is removed and the pin pulled out. The tract is flushed and the hole filled with a surgical sponge soaked in an antiseptic solution and fixed in place with tape. If the pin is fixed within the cast through a dowel or a hoof acrylic pad (see Fig. 81-3), a complete cast change under general anesthesia is necessary. Osteomyelitis may develop as an extension of pin tract infection or at the open ends of the fracture. Treatment of orthopedic infections is discussed in Chapter 88. When osteomyelitis is rampant and uncontrollable, euthanasia may be the only alternative.

Soft tissue swelling occurs frequently in animals wearing an external fixator. This is a normal reaction to the implants, local insult, trauma, and controlled infection. Therefore, adequate distance between the skin and the vertical bars and clamps has to be allowed to accommodate the swelling. This will prevent skin necrosis near contact areas of the clamps.

Pathologic fracture is a common problem encountered in horses treated with the external skeletal fixation device or external fixator.\(^\text{25,26}\) Frequently, a doughnut-shaped cylinder of bone is walled off around the pin (Fig. 81-6). This creates a relatively large defect in the bone and significantly reduces its strength. The bone within the fixator becomes weakened by osteoporosis (disuse atrophy depending on the duration of fixation), and weightbearing on the limb can result in failure through one of the pin tracts (see Fig. 81-6). If the animal is not euthanized at once after failure, the fracture must be treated immediately by either internal fixation or a full-limb cast. Changing the design of the Steinmann pins as well as the threads may limit the recurrence of this complication.\(^\text{27}\)

**Figure 81-5.** Graphic representation of the state-of-the-art design of the external skeletal fixation device developed by Nunamaker and coworkers.\(^\text{19}\) Two tapered transosseous pins are incorporated into the U-shaped apparatus, providing additional stability.
Internal Fixation

At the turn of the 20th century, compression in rigid fixation was recognized as an important component of rapid fracture healing. Rigid internal fixation became an important step in reaching the goal of early return to full function for the fractured limb and the patient. The devastating effects of prolonged external coaptation—"cast disease"—were avoided when this goal was attained. Early return to function allows movement of the joints, associated nourishment of the articular cartilage, and prevention of proteoglycan loss. Additionally, disuse osteoporosis is avoided, and the soft tissues surrounding the fractured bone are maintained in physiologic condition. Early return to function is achieved through anatomic reduction of the fracture and stable internal fixation.

Internal fixation is achieved through opening of the skin. This may occur through a stab incision, as with intramedullary pinning, transcutaneous interlocking, and minimally invasive plating techniques, or through opening the skin over a greater distance, followed by separation of the soft tissues surrounding the fractured bone when bone plates are applied.

Principles

Fracture fragments fixed to each other under compression heal without callus formation. Precise anatomic reduction of the fracture is of paramount importance for this type of bone healing (primary union). It is also critical when the articular surface is involved, because if the reconstruction is not nearly perfect, osteoarthritis will develop (Fig. 81-7).

In the last 50 years, tremendous progress has been made in the art of equine fracture treatment. The greatest influence on this achievement can be ascribed to the AO/ASIF group. Founded in 1958 by four Swiss surgeons, the AO (Arbeitsgesellschaft für Osteosynthesefragen) quickly developed into a worldwide organization. In 1984, the AO Foundation was established, to which all the rights for royalty income were bestowed. Recently, the three manufacturers that supplied surgeons with a large variety of sophisticated, high quality implants (Mathys AG, Bettlach, Switzerland; Stratec Medical, Oberdorf, Switzerland [formerly Institut Strauman, Waldenburg]; and Synthes USA, Paoli, Pa) have merged to form a worldwide single company, Synthes Inc., with its headquarters in Solothurn, Switzerland. For every implant sold, Synthes Inc. pays a certain amount to the AO Foundation to support teaching and the development of new instruments—a genuine approach to the improvement of fracture fixation. Techniques developed for human patients were quickly adopted by veterinarians, and many are applied in daily practice with good success.

The implants, their function, and their application as discussed in this chapter are mainly those developed by the AO group. Included are screws, plates, pins, wires, and specially designed plates and nails. Only the instruments and implants used in equine fracture treatment will be discussed.

Approach to and Manipulation of Bone

Before surgically approaching the bone, a careful radiographic study should be conducted that includes multiple views from a variety of angles. Along with standard radiography, computed tomographic scans may aid in the selection of the locations where implants are applied and the direction of their insertion. Potential interference of interfragmentary screws and plates with soft tissue structures must be considered. In articular fractures, reconstruction of the joint should be the deciding factor in the decision of how to approach the fracture and apply the implants. For some fractures, surgery should not be attempted—for example, a comminuted fracture of the radius with substantial defects in the caudal cortex has no chance to heal.
because continuous cycling of the implants eventually leads to implant failure. It is prudent to conduct a detailed discussion with the owners of equine patients about the chances for a successful surgical outcome, the potential complications, and the costs of the particular fracture repair prior to surgery. Availability of all implants and instruments needed at the time of surgery is an absolute prerequisite for a successful result. The approach to the bone should be carried out rapidly carefully and with respect for Halsted’s principles of good surgical technique. Special attention should be paid to the blood supply, with severance of major blood vessels avoided. The periosteum should be maintained with the underlying bone whenever possible. Periosteum is stripped off the bone only immediately under implants such as plates. Recently developed plates such as the limited contact dynamic compression plate (LC-DCP), the PC-Fix, and the locking compression plate (LCP) are applied over the periosteum (see later). Massive dissection should be avoided, because it facilitates the accumulation of blood and serum. Planning the approach relative to the application of selected implants is of great importance for a successful outcome of the surgery. For example, the approach to the MCIII is made through longitudinal splitting of the common or lateral digital extensor tendon, which facilitates secure closure of the soft tissues and skin over the implants after the fracture is repaired.

In human and small animal osteosynthesis, biological fracture fixation has become very popular. This technique abandons the dogma of anatomic reconstruction and accepts that proper axial and rotational alignment of the bone, despite incomplete reconstruction, followed by fixation of the fracture with strategically placed implants is preferred. Longer plates are used, providing better leverage conditions. Screws are inserted through the holes that are most important biomechanically, but not all holes in a plate are filled with screws. If possible, the plate is pre-bent (to conform to the shape of the contralateral intact bone), slid along the fractured bone through a small incision, and fixed with screws implanted through stab incisions. Such minimal fixation cannot be used successfully in horses. However, the principle of applying the implant by a minimally invasive technique is applicable to the horse, even if the implant has to be modified to meet the demands placed by the horse’s size.

**Instruments**

Basic instruments used for fracture treatment include a variable-speed air or electric drill with forward and reverse gears. To facilitate mechanical preparation of the threads in the bone, switching between forward and reverse should be easy. Drill bits and guides of different types and sizes are needed (Table 81-1). Drill guides allow application of concentric pressure, they stabilize the drill bit, and, in doing so, they prevent breakage. They protect tissues around the hole from frictional trauma generated by the drill bit and the tap. It has been shown that drilling at maximal speed (about 90 psi of air pressure) results in less heat production than drilling at low speeds.

The drill bits should be sharp and should be exchanged frequently, because dull drill bits create heat in the hard and dense equine bone. This is especially true in adult animals. Continuous application of saline solution throughout the drilling procedure is important to reduce heat production. The drill bits are designed to allow penetration of the fluid along their outside perimeter, which facilitates lubrication and reduction of friction. However, not enough water can be flushed into the drill hole to effectively cool the drill bit. Frequent cleansing of the drill bit to remove the swarf material is the single most important factor in reducing heat production. During drilling, axial pressure is applied to the drill bit without bending it. Bending causes the drill bit to become dull too rapidly because of interference with the drill guide. More importantly, the hole will be of a larger diameter than intended. Adequate but not excessive pressure should be applied. The instruments used for screw insertion are discussed in the paragraphs about the lag technique, later.

**Implants**

**Screws**

Various types of screws were developed by the AO together with Synthes Inc. (see Table 81-1) and have different functions. The parts of a screw include the head, shaft, core, and thread. Its attributes include pitch, shaft length, thread length, and total screw length.

**Screw types**

- **Cortex screws** have a 0.7-mm thread width, and a thread length that depends on the screw length (see Table 81-1). A cortex screw does not contain a shaft portion and is referred to as a fully threaded screw. The shaft screw (see Table 81-1) is an exception and therefore a special cortex screw. The shaft screw contains a shaft portion of the same diameter as the outside diameter of the threads.
- **Cannulated screws** contain a central canal for a guide wire (see Table 81-1). The design resembles the cancellous screw, because it has a thinner shaft and a wider thread portion. The 7.3-mm cannulated screw contains a self-drilling and self-tapping tip, as well as a reverse cutting device at the back end of the threads (Fig. 81-8). A recent in vitro study using equine cadaveric femora revealed that the 6.5-mm cancellous and the 7.3-mm cannulated screws vary in insertion properties (the 7.3-cannulated screw requires significantly greater insertion torques), but they have similar pullout properties in the mid, proximal, and distal metaphyses of foal femora. Both screw types have greater holding power at the mid-diaphyseal location than at metaphyseal locations. Because of the overall similar

holding powers of 6.5-mm cancellous and 7.3-mm cannulated screws, it is unlikely that increasing the screw diameter beyond 6.5 mm will provide increased holding power in foal femoral bone. The use of the 7.3-mm cannulated screw should be considered for foal femoral fracture repair when greater accuracy is needed, or when bone threads for the 6.5-mm cancellous screw have been stripped.

Self-tapping cortex screws contain the same thread-cutting device at the tip as the tap, obviating one step of the standard screw insertion technique (see Table 81-1). These screws are popular in human surgery and are gaining more acceptance in equine surgery. A recent in vitro study revealed that the mechanical properties of regular and self-tapping 4.5-mm cortex screws are similar with regard to pullout from the adult equine MCIII, and that the self-tapping cortex screws require less than half the total insertion time required by standard screws. Interestingly, bone failure and bone comminution during the pullout tests were more commonly associated with self-tapping screws.

Locking head screws were introduced with the less invasive stabilization system (LISS) and subsequently also applied in the locking compression plates by Synthes Inc. (Fig. 81-9). The conical shape of the PC-Fix screw (which is no longer manufactured) served as a basis for the new design. The screw head was modified with a threaded profile, which complemented the one in the LISS plate hole. This design provided a stable angular fixation of the screw–plate (fixator) junction: the screw head is self-centering in the hole, and it keeps the screw from backing out of the LISS and LCP fixator (see later). The pitch of the threads at the screw head is identical to that of the threads on the shaft. Because of the larger diameter of the screw head, the pitch seems larger than on the shaft. However, the threads on the screw head catch after turning only 180 degrees instead of 360 degrees in the shaft. This facilitates faster fixation of the screw head in the plate and reduces the development of plate deformation through tightening of the screw.

The screw was also adapted to the unique mechanical demands of an internal fixator. The core diameter of the screw was enlarged to resist the increased bending moments and higher shear forces induced by a fixator. This, plus the threaded screw–plate interface, allows the use of unicortical screw fixation in the diaphysis. The stability of unicortical fixation with locking head screws was established in a cadaveric biomechanical study.

Unicortical screw fixation, in turn, allows the application of self-drilling or self-tapping screws, which was made possible by reducing the thread pitch and adding drill and tap sections to the screw tip (see Table 81-1). These design changes have additional benefits: screw length determination is no longer needed because all diaphyseal screws can be the same length; therefore, screw lengths are not needed in increments of 2 mm, which results in a smaller inventory; pre-drilling and tapping are no longer needed, and the thread profile cut into the bone is more precise (because each screw is used once and therefore the drill and tap parts are sharp), which results in a better anchorage of the screw in the bone.

In the horse, self-drilling and self-tapping screws are rarely used because of their high price, and screws are usually inserted bicortically. Therefore, most of the advantages just listed do not apply to this species. However, self-tapping screws are used in the horse in bicortical applications.

Other screws include the Herbert screw (Zimmer Orthopedics, Warsaw, Ind), an example of a self-contained compression screw. This screw is fully threaded and contains threads not only over its entire length but also on the head. The head is wider than the rest of the screw and

can be completely buried in the bone. It has been used in condylar fractures of MCIII/MTIII.

Recently, a cannulated, tapered, variable-pitch, self-compressing screw was developed (Acutrack Equine Screw, Acumed Veterinary, Hillsboro, Ore). This screw is 45 mm long, and it has a diameter of 6.5 mm at its base that tapers to a diameter of 5.0 mm at its apex. Because of the tapered shape, no glide hole is needed. The screw is manufactured of titanium. Biomedical studies comparing Acutrack to 4.5-mm AO cortex screws inserted in lag fashion revealed that the screws had similar biomedical shear properties.42 The self-compressing action of the Acutrack screw provided only 70% of the compression force achieved with the 4.5-mm AO cortex screw.43 The pushout strength was higher in the Acutrack screw.42 Simulated mid-body fractures of the plating over the screw.30 This is a great advantage, especially compression of the fragments. The screw has such a small reduction of long bone fractures and interfragmentary carpal bone slab fractures. It is also applicable for anatomic 6.5-mm cancellous screw is stripped.

Interesting for the equine surgeon, and they can be used if a 7.0-, and 7.3-mm diameters, but only the latter two sizes are available in three different configurations: with a thread type as well as drill sizes needed are summarized in Table 81-1. For compact equine bone, the 5.5-mm screw was developed. This screw has advantages in adult horses over the 4.5-mm screw.45-47 The 6.5-mm cancellous screw is available in three different configurations: with a thread length of 16 mm, with a thread length of 32 mm, and as a fully threaded screw. Since the introduction of the 5.5-mm cortex screw, the 6.5-mm cancellous screw has diminished in importance, because the 5.5-mm screw can also be inserted when a 4.5-mm hole has been stripped. A stripped 5.5-mm hole can still be engaged by a 6.5-mm cancellous screw. Cannulated screws are manufactured in 3.5-, 4.5-, 7.0-, and 7.3-mm diameters, but only the latter two sizes are interesting for the equine surgeon, and they can be used if a 6.5-mm cancellous screw is stripped.

The 3.5-mm cortex screw is used to achieve interfragmentary compression of certain fractures, such as third carpal bone slab fractures. It is also applicable for anatomic reduction of long bone fractures and interfragmentary compression of the fragments. The screw has such a small head that it can be completely buried in bone, which allows plating over the screw.48 This is a great advantage, especially if two plates have to be applied.

The recently developed locking-head screws are the strongest screws available for equine fracture treatment, because of their large core diameter (4.3 mm). These screws can be applied only through the LISS and the LC-plates. They are available as nontapping; self-tapping; and self-drilling, self-tapping screws. Only the first two types are of interest for equine surgeons. The self-drilling, self-tapping screw is very expensive, and because of its design it is impossible to predetermine the depth of the screw hole. Also, in equine fracture treatment it is important to achieve screw purchase in both cortices. If a self-drilling, self-tapping screw were inserted, the sharp self-drilling part of the screw would protrude out of the trans-cortex, which could produce soft tissue damage.

**Functions**

Screws can be used as lag screws, position screws, and plate screws.44 There is a difference between a partially threaded cancellous or cannulated screw, which automatically produces a lag effect, and a cortex or shaft screw used in lag fashion.3 The cancellous and cannulated screws are inserted in such a manner that all of the threads pass the fracture line. Thus, tightening of the screw provides interfragmentary compression. The preparation of the screw surface plays an important role in the holding power of the implant.45 Special surface preparation of stainless steel and titanium screws showed superior holding characteristics over the plain stainless steel and titanium screws.45

The lag technique is used to place cortex screws so that they act in lag fashion. This technique is not necessary when using partially threaded screws (such as cancellous or cannulated screws) as lag screws when applied as discussed in later paragraphs. The cis-cortex or near cortex is drilled with a drill bit having the same diameter as the outside thread diameter of the screw (Fig. 81-11, A). This is referred to as overdrilling. Therefore, at insertion of the screw, the threads do not engage bone in that cortex but glide through, so this portion of the hole is called the glide hole. The insert drill

![Figure 81-10. Lag screw technique. A, A cancellous screw of the correct thread length. All threads are located past the fracture plane, allowing interfragmentary compression. B, Selection of a cancellous screw with too long a thread length. Threads are located on both sides of the fracture plane, preventing interfragmentary compression. (From Nixon AJ: Equine Fracture Repair, Philadelphia, 1996, WB Saunders.)](image-url)
sleeve is designed to have an outside diameter that is the same as that of the glide hole, and an inside diameter that is the same as that of the smaller drill bit, which has a diameter identical to that of the core of the screw. Insertion of this drill sleeve into the glide hole ensures concentric drilling and accurate reduction of the fracture (see Fig. 81-11, B). The hole drilled through this sleeve across the trans-cortex or far cortex is referred to as the thread hole.

To allow a greater contact area between the screw head and the bone, a depression is created at the near cortex using the countersink (see Fig. 81-11, C). This decreases stress concentration at the screw head–bone interface. It is important to use the countersink in a 360-degree motion rather than in a to-and-fro motion; otherwise, an imperfect indentation is cut, preventing proper seating of the head. Countersinking is especially important in screws inserted at nonorthogonal angles relative to the surface of the bone. Care is taken to insert the nozzle at the tip of the countersink axially into the glide hole, and to remove the bone making contact with the instrument. If this is not done, tightening of the screw results in stress accumulation at the screw–thread junction, and bending of the screw head is possible.

The depth gauge is then used to determine the total length of the screw, including the head (see Fig. 81-11, D). Therefore, the length of the screw is measured to include the head. The depth gauge has a small hook at the end of its thin shaft that is inserted through the thread hole. By slightly tilting the instrument to one side, the hook catches the opposite cortex, and by sliding the movable portion toward the countersink depression, the exact length of screw is determined. Using the tap sleeve to protect the soft tissues as well as to help guide the tap, the tap is inserted into the glide hole and the threads are cut into the thread hole (see Fig. 81-11, E). The threads are cut by advancing the tap three half-turns clockwise, followed by one half-turn counterclockwise. The counterclockwise action allows transport of the swath material into the flutes of the tap and ensures precise cutting of the threads without interference of the swath material cut from previous threads. An experienced surgeon may tap the thread hole with the air drill (power tapping) to speed up the procedure. This is especially advantageous when many screws are to be inserted. It requires experience, however, or serious complications may arise, such as stripping of the thread holes, cross threading of

Figure 81-11. Lag technique, shown on a lateral condylar fracture of the distal MCIII. A, The cis-cortex is overdrilled. B, The insert drill bit is placed into the glide hole and advanced past the fracture plane, and the concentric thread hole is drilled across the trans-cortex. C, A depression for the screw head is prepared with the countersink. D, The required length of the screw is determined with the depth gauge. E, The threads are cut into the thread hole with the tap. F, The screw of predetermined length is inserted and solidly tightened with the hexagonal-tipped screwdriver. (From Nixon AJ: Equine Fracture Repair, Philadelphia, 1996, WB Saunders.)
the tap, and instrument breakage. If a self-tapping screw is used, this step is not necessary. The small AO air drill is not powerful enough to insert a self-tapping screw without applying a to-and-fro “power-tapping” technique. The AO compact air drill, however, has one-third more strength and easily inserts self-tapping screws without to-and-fro activity.

Once the hole has been tapped, it is flushed to clean the hole and to provide lubrication. A screw of the predetermined length is inserted, using the hexagonal tipped screwdriver (see Fig. 81-11, F) either by hand or with an air drill. Final tightening is always carried out by hand. Care is taken to avoid excessive force, which may result in failure of the screw head, or in stripping of the threads cut into the thread hole.16 This is not a common problem in dense equine bone. The shaft screw is inserted by applying the identical lag technique. However, care has to be taken that the glide hole is made slightly longer than the shaft screw. If the shaft is longer than the glide hole, no interfragmentary compression is achieved.

In the lag screw technique, a lag screw (either a partially threaded cancellous screw or a cannulated screw) is inserted after using a drill bit of only one size across the entire bone. Threads are cut along the total length of the hole with the cancellous tap, and the lag screw is inserted. The threads in the cis-cortex should not be engaged by the screw threads but only those of the trans-cortex, allowing achievement of interfragmentary compression.1-3 Because the hardness of equine bone makes screw insertion difficult, it may be advisable to enlarge the cis-cortex with a 4.5-mm-diameter drill bit after first drilling the entire hole with the 3.6-mm drill bit.

Insertion of cannulated screws employs the same technique. However, the initial step involves placement of a guide wire in the desired location. A special drill sleeve allows insertion of parallel screws close together. It is advisable to pre-drill equine cortical bone with a small drill bit before insertion of the guide wire to avoid bending it. All instruments are cannulated to accept the guide wire. The size of the drill bit depends on the size of the screw to be implanted and the size of the guide wire. Once the guide wire is in place, the measuring device is placed over the portion protruding out of the bone. The length of guide wire located in the bone is determined, and this is the length of screw required. It is advisable to select a screw 5 mm shorter than the length of the guide wire, to ensure secure seating of the wire throughout the implantation procedure. Subsequently, the cannulated drill bit is placed over the guide wire and the hole of predetermined length is prepared. The hole is tapped and finally the selected screw is inserted and firmly tightened (Fig. 81-12). An alternative method is to drill a pilot hole, insert the guide pin, and drill the hole the correct length (Fig. 81-12). At the end, the guide wire is removed.

Figure 81-12. A capital femoral fracture is repaired with three cannulated screws. After the screws are inserted over a guide pin and tightened, the guide pins (which penetrated further than the screws) are removed.

The 7.3-mm cannulated screw has a self-drilling and self-tapping tip. Therefore, a screw of predetermined length is inserted without drilling a thread hole. Because of the initial insertion of the guide pin and the ability to select a screw of correct length, the danger of implanting a screw that is too long and protrudes out of the opposite side of the bone is negligible. In equine bone, insertion occurs in the same manner as tapping, meaning that the screw is advanced into the bone in the same manner as tapping, meaning that the screw is advanced into the bone, providing friction and stability.

The position screw is used to maintain two pieces of bone at a certain distance apart and to prevent interfragmentary compression. This is achieved by drilling a hole of only one size (thread hole) across both cortices, followed by tapping. Only fully threaded cortex screws may be inserted as position screws. Because the threads catch in the cis- and trans-cortex, interfragmentary compression is prevented. No lag effect is achieved.

The plate screw is inserted by the technique described for the position screw. Any type screw may be used in this manner. With the plate screw, the plate hole serves as a glide hole and allows compression of the plate onto the underlying bone, providing friction and stability.

Screw removal
Cortex and locking-head screws are easily removed because of their fully threaded design. Similarly, shaft screws are easy to remove, because the shaft completely fills the glide hole. However, after a fracture has healed, a cancellous screw may be impossible to remove from hard equine bone, because during fracture healing, the pre-cut threads in the cis-cortex fill in with solid bone. Removal of the screw necessitates that the threads cut their own way through the bone, a task for which they are not designed. This frequently results in the screw breaking, usually at the head–shaft or the shaft–thread junction. Therefore, cancellous screws should not be used when implant removal may be necessary at a later stage. Smaller cannulated screws have the same problem as cancellous screws. The 7.3-mm cannulated screw, however, contains a reverse-cutting edge at the caudal end of the threads, which facilitates re-tapping of the bone threads during screw removal13 (see Fig. 81-8).

Occasionally, the hexagonal indentation in the screw head may be stripped during screw removal. This occurs if the screwdriver is improperly inserted in the hexagonal hole. Alternatively, if the hole is partially filled with tissue, the screwdriver cannot be inserted completely. Subsequent application of extraction force (counterclockwise motion on the screwdriver) may strip the hole. This problem is mainly encountered with the 3.5-mm screw because of its smaller
screw head. A special screw retrieval instrument has been designed for such situations (Fig. 81-13). A shaft with a conical, threaded tip is inserted into the hexagonal indentation of the screw head. The threads of the tip have a reversed orientation compared with the screw threads. Therefore, when the cone is tightened in the screw head with a counterclockwise motion, an extraction force is applied to the screw, allowing it to be easily removed. These screw-retrieval devices are available for all sizes of screws.

When a screw head is broken off, a special hollow drill bit is available to remove the bone surrounding the screw. Because it rotates counterclockwise, the threads on the inside of the hollow drill bit interlock with the screw, and advancing the drill bit removes the broken screw.

**PLATES**

The first plates to contain an axial compression device were developed by Danis in 1947. They consisted of a plate with an oblong hole on one end. At the head of the plate, a compression screw could be introduced, which pushed the screw placed through the oblong plate hole toward the fracture line and in doing so provided axial compression to the fractured bone ends (Fig. 81-14). Ten years later, Bagby introduced an impacting bone plate. The heads of the screws he designed had a conical underside. If the screw was inserted eccentrically into the plate hole, the conical underside made contact with the edge of the plate hole. By tightening the screw, the bone into which the screw was implanted was displaced toward the fracture site and thus induced axial compression (Fig. 81-15). The first plates developed by the AO in 1958 contained round holes (Fig. 81-16). Axial compression was applied with the help of a tension device (see later). Plate hole designs are shown in Figure 81-16 and described in the following paragraphs.

**Standard plates: LC-DCP**

The dynamic compression plate (DCP), up to now the workhorse for equine fracture treatment, is being replaced by the limited contact dynamic compression plate (LC-DCP), especially in the United States. Studies in human medicine showed the DCP to cause osteoporosis development under the plate, although this is not encountered in equine surgery (see later). This led to the development of biologically improved plates.

In the conventional DCP, the plate holes provided the least resistance to failure. This problem was somewhat offset in equine fracture treatment by inserting screws through all plate holes. By designing a plate that contained at each cross-section along its entire length the same amount of metal, an implant of uniform bending stiffness was developed. To achieve this, half-moon-shaped pieces of metal were removed from the underside of the plate. This resulted in limited contact between bone and the plate, which led to the name of the plate: LC-DCP (Fig. 81-17). The limited contact surface was welcomed in human surgery to fight the problem of osteoporosis developing under the plate. Extensive tests comparing the LC-DCP with the conventional DCP revealed that the LC-DCP had an equal bending stiffness and a 50% increase in the continuity of the bending stiffness. This reduces local stress concentration near fracture gaps. Additionally, the blood supply of the bone under the plate was significantly improved. Mechanical tests revealed that the design of the LC-DCP provided increased resistance to cycling failure compared with the DCP. The undercuts of the plate allow the development of some callus bridges over the fracture gap, which lead to a
significant increase in stability, despite the fact that these bridges are small. The trapezoidal cross-section allows the formation of shorter but stronger bone lamellae on either side. Also, it prevents the bone from growing over the plate. The dynamic compression unit (DCU) hole design in the LC-DCP, which allows axial compression to be applied from either side of the hole, replaced the conventional DCP hole design (see Fig. 81-16). This allows the distribution of the plate holes evenly along the entire plate and obviated the need for a center in the plate. The DCU hole is also undercut at each end to allow the insertion of screws up to a 40-degree angle relative to the orthogonal direction. In the DCP hole, only a 25-degree angulation can be achieved.

There are two plate widths: the narrow, with the holes arranged in a straight line, and the broad, with alternating offset holes. Pertinent data on width, length, and hole distribution in these plates are summarized in Table 81-2. Recently, a special equine LC-DCP (see Table 81-2) made from thicker plate stock was developed for application during arthrodesis of the metacarpophalangeal joint (see Chapter 85). This plate is available in all sizes and will undoubtedly be very popular among equine orthopedic surgeons.

The DCU holes are specially designed to allow dynamic compression as the screw is tightened. The holes are arranged according to the spherical gliding principle, with an incline, or slope, toward the center portion of the plate (Fig. 81-18). When a screw is inserted in a far (load) position (offset 1 mm from the center of the hole), the screw head contacts the plate at the top of this incline. With tightening, the screw head "slides down the slope" until it comes to rest at the bottom of the incline, in the center of the oblong screw hole. Because the screw is introduced into the bone, screw movement toward the fracture line results in compression of the fractured bone ends. This offset drilling can be carried out on either side of each hole and therefore on either side of the fracture line (see Fig. 81-15). The application of the LC-DCP requires the use of the special LC-DCP double drill guide identified by its undercuts on the handle, identical to the ones under the plate itself (Figs. 81-19 to 81-21). (Note: the DCP drill guide should not be used with the LC-DCP.) An alternative to the LC-DCP drill guide is the universal drill guide, which contains a spring-loaded tip (see Fig. 81-19). Pressing down on the drill guide places it near the center of the hole (Fig. 81-22). Placing the spring-loaded tip on the far end of the DCU hole relative to the fracture line allows a 1-mm compression of the fracture line.

The technique of application is as follows. The fracture is reduced (Fig. 81-23, A), and it is maintained in that config-

---

**Figure 81-16.** The plate holes designed for Synthes plates. A, The initially developed round hole. B, The dynamic compression plate hole, which allows compression from one side. The screws can be angulated axially up to 25 degrees. C, The dynamic compression unit hole, which allows compression from either side and is used in the LC-DCP. The screws can be angulated axially up to 40 degrees. The plates have undercuts. D, Locking head plate holes used in the LISS plate, allowing only orthogonal insertion of the screws. The plates have undercuts. E, The Combi-Hole used in the locking compression plate allows the insertion of locking head screws—as shown here—and standard screws. The plates have undercuts and a pointed end that allows minimally invasive insertion through a small incision.

**Figure 81-17.** 5.5 LC-DCP. The ends are pointed, the screw holes are arranged in two slightly offset rows (top side of plate shown above), evenly distributed along the plate, and the underside of the plate (shown below) contains undercuts.

**Figure 81-18.** Design of the dynamic compression unit (DCU). Both sides of the hole are shaped like an inclined cylinder. Like a ball, the screw head slides down the incline. Because the screw head is fixed to the bone via the shaft, it can move only vertically relative to the bone. The horizontal movement of the head, as it impacts against the angled side of the hole, results in movement of the bone fragment relative to the plate and leads to compression of the fracture. With the DCU, compression can be achieved on either side, obviating the need for the plate to have a center, as in the dynamic compression plate.
The threads in the glide hole cut into the cortex and prevent any gliding. To correct this undesirable effect, the shaft screw was developed. The shaft, which fills out the glide hole completely, does not cut into the cortex.

Any cortex or shaft screw can be inserted under load (at the far end of the oblong plate hole) or in neutral position (at the center) of each plate hole. Under load, 1-mm centripetal displacement or compression of the fracture gap is implemented. In neutral position, 0.1-mm compression is achieved. If double plating is applied, only two screws are placed under load in the second plate, which in most cases is arranged at 90 degrees relative to the first plate.

Plates are contoured with the help of a plate-bending press to fit the surface of the bone. A perfectly contoured plate, however, compresses only the cortex immediately under the plate, whereas the opposite cortex remains decompressed (Fig. 81-24, A). By slightly overbending the plates at the fracture site (see Fig. 81-24, B), compression is achieved along the entire circumference of the bone. Axial interfragmentary compression under a plate may also be implemented with the help of a tension device (Fig. 81-25). The plate is applied to the bone with several screws in neutral position on one end of the fracture. The tension device is hooked into last hole on the other end of the plate and attached to the underlying bone through a unicortically applied 4.5-mm cortex screw. With the help of a wrench, the tension device is tightened, which pulls the plate toward the tension device and thus applies compression to the fracture site. Once adequate compression is applied, screws are inserted on the other side of the fracture through the plate in neutral position and tightened. The tension device is subsequently removed and the remaining screws are inserted in empty plate holes.

The stability of the fixation is derived from friction between the implants and the bone. A technique called plate luting has been developed to obtain 100% plate–bone contact by applying bone cement (methylmethacrylate) between the plate and the bone. This is achieved after all the screws of the plate are inserted. All the screws are then loosened, the plate is lifted off the bone, the soft bone cement is placed underneath it, and the screws of the plate are retightened preferably with the power drill. Entrance of bone cement into the fracture line must be prevented because it retards or prevents bony union in that area. Once the screws are tightened, the soft cement fills the oblong plate holes around the screw heads and provides additional support, making the fixation extremely rigid. When only the oblong plate holes are filled with bone cement, a similar but lesser increase in strain protection occurs. Excess bone cement is rapidly and carefully removed. Plate luting is especially useful on bones with anatomically complex surfaces that make contouring of the plate difficult. The addition of gentamicin into the bone cement facilitates long-term release of this antibiotic and provides effective protection against postoperative infections (see Chapter 88).

Plate luting is not used in humans and small animals because vascular necrosis of the bone develops under the plate, resulting in pathologic fractures after implant removal. This complication has not been reported in horses.

Screws should be inserted perpendicular to the surface of the bone. If a second plate is used, it should be positioned to allow the screw holes to be located between the screws of the other plate. This reduces the likelihood of

Figure 81-19. The LC-DCP double drill guide (top) contains undercuts like those of the corresponding plate to distinguish it from the DCP double drill guide. The dark ring represents the neutral (green) guide, the light ring the load (yellow) guide. The universal drill guide (bottom) contains a spring-loaded guide for the thread hole and a larger guide of the glide hole. The universal drill guide is available for the different screw sizes.

**Figure 81-22.** A, The universal drill guide placed into a dynamic compression unit (DCU) hole without applying pressure onto the guide. Viewed from below, the hole in the guide can be seen very close to the right end of the DCU hole. B, The universal drill guide placed into a DCU hole under pressure. The spring-loaded part of the guide is sticking out on top. From below, a gap can be seen between the hole in the guide and the right end of the DCU hole.
Figure 81-23. Repair of a simple oblique MCIII fracture with two cortex screws applied in lag technique combined with a broad LC-DCP as neutralization plate. A, The large pointed reduction forceps maintains alignment of the fractured bone during implantation of the two 3.5-mm cortex screws. B, The two screws are implanted and the reduction forceps removed. C, A 10-hole broad DCP is applied to the dorsolateral aspect of the bone, distal from the two interfragmentary 3.5-mm cortex screws. The plate was overbent at the fracture site, allowing introduction of an aluminum template between the bone and the plate. D, A thread hole is drilled across the bone through the second most distal plate hole with the help of the yellow, load drill sleeve. E, The screw is inserted but not completely tightened, followed by preparation of an identical hole at the opposite end of the plate. F, The second screw is inserted and both are alternately tightened, placing the fracture under axial compression. The remaining screw holes are prepared through the green, neutral drill guide. G, A lag screw is implanted across the fracture plane. H, All the screws are tightened. (From Nixon AJ: Equine Fracture Repair, Philadelphia, 1996, WB Saunders.)

inadvertent contact between the screws of the two plates. Every hole in a plate should be filled with a screw. 29 Should a hole traverse a fracture line, the lag technique should be applied by overdrilling of the cis-cortex, and the screw should be directed in such a way that it engages the opposite cortex next to the fracture line. Where no support can be achieved in a cortex, bone cement may be placed and the screw implanted. After the cement hardens, the screw will be solidly fixed.

Application of 4.5-mm screws through a 4.5-mm plate allows angulation in the longitudinal direction of about 40 degrees, and 7 degrees laterally. 52 Application of a 5.5-mm screw through the same hole allows an angulation of only about 25 degrees in the longitudinal direction. The plates applied for fixation of a long bone fracture ideally extend over the entire length of the bone. 4 Shorter plates must be staggered to ensure plate coverage of the total length of the bone. The most distal end of the proximal fragment in an oblique long bone fracture should be wedged between a plate and the opposing distal fragment. Therefore, the configuration of a fracture dictates to a certain extent the location of the plate to be applied (not just the tension side of the bone; see later). 29 Implants should be applied at a distance from severely bruised skin or areas of frank skin defects.

Plate functions include compression, neutralization, tension-band, and buttressing. The design of a plate does not dictate its function, because the same plate may be used for different functions and a plate may serve more than one
function at a time. The compression and neutralization functions are the most frequently applied. When a plate serves in compression function, two screws on either side of the fracture line are placed under a load. A plate serves a neutralization function after anatomic reconstruction and interfragmentary compression of a simple or comminuted fracture is accomplished by several screws placed in lag fashion. The various diverging shear, bending, and rotational torque forces converging on these screws are neutralized by one or two plates. Such plates effectively bridge the proximal and distal aspects of the bone and protect the fixed fracture. The screws are inserted in the neutral position. Application of neutralization plates has to be planned ahead of time to avoid interfering with the reduction screws or eliminating options for their placement. Most plates applied satisfy both compression and neutralization functions.

A plate applied in the tension-band function transforms the tensile forces applied to the fractured bone underneath into compressive forces. The classic example of such a plate is one that is applied to fix an olecranon fracture. Because these plates are subjected mainly to tensile forces, smaller plates may be applied in these situations than for plates used in compression or neutralization functions.

Cortical bone defects that persist after anatomic reconstruction of the fracture cause instability of the repair because of stress concentration. Such areas need to be protected and bridged by an implant, maintaining length by preventing collapse of the fixation (Fig. 81-26). A plate applied in such a fashion is called a buttress plate. It is advisable to fill the defect in the bone with a cancellous bone graft or bone replacement material. Any screw placed through the plate in the region of the defect should engage the trans-cortex. All the other principles for plate fixation are applied.

Special plates
The DCP, as mentioned, has played a key role in establishing the guideline for plate fixations of fractures in humans, small animals, and horses. After being replaced by the LC-DCP as the standard plate, its use will diminish. Table 81-2 summarizes the pertinent data of the most frequently used DCPs. These plates may be applied in all situations described for the LC-DCP. The DCP holes contain an incline on one side, which allows 1 mm of compression to be applied by drilling an eccentric hole (see Fig. 81-16).

Figure 81-24. Application of a plate onto a bone. A, If a plate is perfectly contoured to the surface of the bone, a narrow gap develops at the fracture site opposite the plate after insertion and tightening of the screws. B, To overcome this problem, the plate is overbent (prestressed) about 1 mm, right at the fracture site. C, When the screws are reinserted the entire circumference of the fracture is under compression.

Figure 81-25. A, The tension device is hooked in the last plate hole. B, The device is attached to the bone with a short screw. C, Twisting of the hexagonal screw head pulls the plate toward the left side and applies axial compression to the underlying fracture.

Figure 81-26. Comminuted mid-shaft fracture of MCIII showing a bone defect. The defect is filled with cancellous bone graft and a broad 12-hole LC-DCP is applied over the defect in buttress function. For better visualization, the dorsally applied LC-DCP, routinely used in a clinical case, is not shown.
Therefore, the plates have a center, on either side of which the DCP holes are arranged such that the incline is located at the far end of the holes. The plates have to be applied so that the center of the plate is positioned over the fracture site whenever possible.

One-third tubular plates are very thin and, depending on the size of the hole, may be applied with a 3.5- or a 4.5-mm screw (see Table 81-2). The 3.5-mm plate is applied, using standard technique, in fracture treatment of proximal MCII, MCIV, MTII, and MTIV fractures in adult horses, and of nondisplaced ulnar fractures in very young foals.

T-plates are available for 4.5- and 5.5-mm screws as well as in a smaller version for the 3.5-mm screws. These plates are suited to areas where tension is applied without bending and sufficient space is not available for the application of a straight, regular plate. T-plates have been used for arthrodeses of the tarsometatarsal and distal intertarsal joints.

Dynamic condylar screw (DCS) and dynamic hip screw (DHS) plates are used in implant systems that were developed on the principles of the angled blade plate (ABP). These plates consist of a long lag screw with a 12.5-mm thread width, a 25-mm thread length, and an 8-mm shaft diameter. The shaft is flattened on two opposing sides to prevent rotation of the screw after it is introduced into the barrel of the plate. The DCS/DHS screw is inserted at a predetermined angle (95 degrees for the DCS plate and 135 degrees [standard] for the DHS plate) (see Table 81-2). The most important step in the application of the DCS and DHS plate systems is the correct insertion of the 2.5-mm guide pin. Drill guides aid in the placement of the guide pin, which is best verified intraoperatively with an image intensifier. (Intraoperative radiographs, despite being more time consuming, are satisfactory as well.) Pre-drilling of the cortex with a 2.5-mm drill bit facilitates insertion of the guide pin. Care has to be taken that all of the four points on the base of the drill guide under the handle are in contact with the bone during drilling, even if the drill guide tip does not make contact with the underlying bone (Fig. 81-27, A). Tilting of the drill guide with its tip down to bone results in false orientation of the DCS screw, which prevents the plate from making contact with the bone. This will require complicated adjustments of the plate angulations to make the plate contact the bone and will prolong the surgical procedure. If the plate barrel junction is not in direct contact with the bone, the gap may be bridged with polymethylmethacrylate (PMMA). Once the guide pin is correctly placed, the subsequent steps are easily accomplished because all instruments are hollow and accept the guide pin.

The measuring device is placed over the guide pin, and its depth in the bone is determined (see Fig. 81-27, A). The triple reamer placed over the guide pin allows simultaneous drilling of the core hole, the portion for the plate barrel, and the beveled plate-barrel interface (see Fig. 81-27, B). The reamer is assembled and adjusted to a length measuring 5 mm less than the pin portion located within the bone. This ensures persistence of the pin in its position throughout the screw insertion procedure. After preparing the screw hole, the threads are cut using routine technique (see Fig. 81-27, C), and the screw of appropriate length is introduced, followed by application of the plate (see Fig. 81-27, D). Once the shaft of the screw and the barrel are aligned, the barrel slides easily over the shaft and the plate position can be adjusted before impacting it onto the bone (see Fig. 81-27, E). The barrel has the same inside diameter as the screw shaft cross-section (8 mm and flattened at two opposite sides). The DCS plate has a barrel length of 25 mm, whereas the standard DHS has a barrel length of 38 mm. A special version of the DHS plate has a 25-mm barrel length as well. After their implantation, the lag screw and the plate are joined with a connecting screw, making the two components work as one unit (see Fig. 81-27, F). Tightening of the connecting screw creates interfragmentary compression, provided the lag screw has passed the fracture line.

Currently, the DHS plate is the strongest plate available in the AO-System. The DCS and DHS plates are versatile, rapidly implanted, and a real asset to large animal surgery, especially when treating long bone fractures in adult horses. The DCS system is useful in metaphyseal fractures of the MCIII or MTIII (Fig. 81-28), the proximal radius, and even the femur. The DHS may be applied for arthrodesis of the metacarpophalangeal joint (see Fig. 81-29) and in selected femoral fractures. Combined with 5.5-mm screws, these plates produce extremely strong fixations.

The PC-Fix plate, which is presently not manufactured, is mentioned here for historical purposes, because it represented the first type of internal fixator developed by Synthes Inc. It was manufactured from pure titanium, and it had round, conical screw holes, evenly distributed along the plate, and a specially designed underside that represents a further development of the LC-DCP. One row of points is arranged along either side of the plate, with the points being located between two plate holes. Between two points, the plate is undercut in an arcuate pattern, similar to the LC-DCP but to a greater extent. The short unicortical screws contained a conical head that locked in the plate hole while being tightened, forming a solid unit between plate and screws, without applying any load onto the screw threads (Fig. 81-29). The first clinical tests conducted with the PC-Fix were done on large animals, mainly cattle (Fig. 81-30). The subsequently developed PC-Fix II was manufactured only as a 3.5-mm implant system. It had a slightly altered plate design and was applied with self-tapping screws. A special plate-bending device was developed to prevent altering of the plate holes during bending. Development of this system led to the next generation of titanium implants: the LISS.

The less invasive stabilization system (LISS) consists of a forged titanium plate, which cannot be bent, and self-cutting, self-tapping titanium screws of predetermined length. The shape of the plate is predetermined and forged accordingly. A guide system for transcutaneous insertion of the screw is mounted on the plate head (Fig. 81-31, A). The screw is inserted into the plate through a small surgical approach at one end of the bone and subsequent advancement of the plate along the periosteum, therefore bridging the approximately reduced fracture. Once in place, the last plate hole is approached through a stab incision and connected through the last hole in the aiming device with a drill sleeve, which is threaded into the plate. This establishes a solid frame, which maintains its angles during screw application and ensures that the screws are inserted orthogonally relative to the long axis of the plate and may be threaded into the plate holes. The remaining screws are inserted transcutaneously through stab incisions. An
Figure 81-27. Application of an LC-DCP and a dynamic condylar screw (DCS) plate to a radius fracture. A, The fracture is initially repaired with two interfragmentary 3.5-mm cortex screws, applied in lag fashion. Subsequently, a 14-hole LC-DCP is applied to the cranial bone surface (tension side) under compression. The guide pin (b) is applied through the special drill guide (a). The measuring device (c) applied over the guide pin allows determination of the length of the pin inserted in the bone (70 mm). B, The DCS-triple reamer is assembled and set for the 65-mm drilling depth, which is 5 mm less than the pin length in the bone and ensures maintenance of the pin during DCS screw insertion. The triple reamer is placed over the guide pin (a) and the shaft hole for the DCS screw (b), the barrel hole for the plate (c), and the barrel-plate junction (d) are prepared. C, The DCS centering sleeve (c) is placed over the tap (b), which is subsequently placed over the guide pin (a). After inserting the centering sleeve into the barrel hole, the tap is advanced to the desired depth (65 mm). D, The DCS coupling screw (d) is placed through the T-handle and the DCS plate (e) is selected (12-hole), and connected to the DCS screw (b) of the desired length (60 mm). The centering sleeve (c) is applied over the coupling screw. After placing the assembly over the guide pin, the screw is inserted to a depth of 65 mm, which is marked on the centering sleeve as 5 mm. E, After tightening the screw and adjusting the horizontal bar of the T-handle parallel to the long axis of the bone, the DCS plate is seated over the shaft of the DCS screw with the help of the DCS impactor (a) and a mallet (not shown). Orientation of the instruments and implants is important, because the DCS screw (left insert) and the plate barrel (right insert) contain complementary parallel contours, which have to be aligned to allow sliding of the barrel over the screw shaft. F, The DCS compression screw is inserted through the plate barrel, inserted into the back end of the DCS screw, and tightened. This unites the three components (DCS screw, DCS plate, and connecting screw) into one unit. Insertion of all remaining screws and tightening of them completes the procedure.
anatomic plate–bone interface is not important, because the screw heads interlock through a thread system with the plate, establishing a solid internal fixator. If the correct implant is selected, implantation of the system is efficient. This system is especially well suited to foals. A successful fixation has been accomplished in a tibial fracture in a calf68 (see Fig. 81-31).

The locking compression plate (LCP) is an implant system that combines the two treatment methods in one implant: compression plating and internal fixators.69 The individual construction elements in this new implant system have individually proved extremely valuable in clinical practice in human and veterinary applications alike. The combination of these elements into one implant system has been made compatible with the majority of existing instruments and conventional screws. The surgeon is free to select the function best suited for the fracture to be treated.

The LCP uses a Combi-Hole, which is a combination between a DCU and a LISS hole (see Fig. 81-16). The surgeon may select the type of screw to be inserted at any given place—either a 4.5-mm or a 5.5-mm cortex screw (or even a cancellous screw) at an axial angle up to 40 degrees, or a locking head screw with a thick core and thin threads and additional threads at the screw head. The locking head screw, however, has to be inserted orthogonally relative to
the long side of the plate. The plate contains also a beveled end at either side to allow insertion through a small incision and sliding of the plate along the periosteum of the fractured bone. A special tissue spreader has been developed to prepare the future plate bed. The thin beveled end separates the soft tissues from the periosteum. The screws may subsequently be implanted through minimally invasive stab incisions.

The clinically available LCP represents a breakthrough in internal fixation (Fig. 81-32). The implants are available in stainless steel in all sizes (see Table 81-2). The fracture fixation has to be planned ahead, because the locking screws cannot be angled in an ideal direction and therefore require solid cortical bone for purchase. Because the strength of a screw is dependent mainly on the core diameter and not thread width,64 the thicker core of the locking screws and the thin threads make the screw several times stronger than the conventional cortex screws. A recent study revealed that the LCP is significantly stiffer than the DCP, the equine LC-DCP, and the clamp-rod internal fixator (not discussed here), making it the implant of choice for most long bone fractures if cost is not a factor.70 Alternatively, attempts are presently underway to develop the PC-Fix as a veterinary-implant-only, with costs compatible with equine surgery.68

Addendum
Thorough knowledge of the basic principles of internal fixation, as well as familiarity with the instruments and numerous implants, is a prerequisite for successful surgery. Everyone interested in treating long bone fractures should register for a basic and advanced AO/ASIF course on internal fixation.

CERCLAGE WIRE
Cerclage wire is used frequently in humans and small animals.71,72 Tension-band fixations with pins and wire are often carried out in dogs and cats. Cerclage wires are also applied around oblique long bone fractures in small animals. This type of fixation has not been successful in horses because of a lack of stability and breakdown of the fixation. However, cerclage wires may be applied in a few situations. Proximal sesamoid fractures can be successfully treated with cerclage wires.73 Also, this type of fixation has been used in connection with small Steinmann pins to provide temporary stabilization of comminuted long bone fractures prior to plate and lag screw application.3

One frequent application of cerclage wire is growth retardation surgery, even though the wire is not applied in cerclage fashion (see Chapter 89). Cerclage wires have been used to treat nondisplaced ulnar fractures in foals.74,75 The wires are passed through holes placed in the frontal plane across the proximal and distal fragments of the ulna. A small loop created before entering the hole in the distal fragment allows even tightening on both sides of the bone after the wire is applied in figure-eight fashion, and the ends are twisted together. This type of fixation results in reduced trauma to the ulna and radius, and it avoids inadvertent fixation of the ulna to the radius, which can occur when using a plate in a young foal. (This may induce subluxation of the cubital joint.) A total of three to four figure-eight wires are applied.

Cerclage wire is used in arthrodeses of the fetlock joint. A frequent application of cerclage wire is growth retardation surgery, even though the wire is not applied in cerclage fashion (see Chapter 89). Cerclage wires have been used to treat nondisplaced ulnar fractures in foals. The wires are passed through holes placed in the frontal plane across the proximal and distal fragments of the ulna. A small loop created before entering the hole in the distal fragment allows even tightening on both sides of the bone after the wire is applied in figure-eight fashion, and the ends are twisted together. This type of fixation results in reduced trauma to the ulna and radius, and it avoids inadvertent fixation of the ulna to the radius, which can occur when using a plate in a young foal. (This may induce subluxation of the cubital joint.) A total of three to four figure-eight wires are applied.

Cerclage wire is used in arthrodeses of the fetlock joint. In comminuted fractures of the proximal sesamoid bones associated with complete breakdown of the suspensory apparatus, a tension band is inserted in figure-eight fashion through the palmar/plantar aspect of the metacarpophalangeal joint, prior to applying the dorsal plate76 (see Chapter 85).
Wire tightening is carried out with utmost prudence. Initially, the wires are loosely twisted by hand. Then, with a pair of flat pliers, the two ends are grabbed, pulled at a right angle away from the bone and, while decreasing the pulling force, evenly twisted around each other. Care must be taken not to twist one wire end around the straight end of the other wire (this type of fixation slips off under tension). Overtightening may result in wire breakage and breakdown of the fixation.

**CABLES**

Two types of cables have been introduced into orthopedic surgery as treatment modality for specific fractures. Ultra-high-molecular weight polyethylene (UHMWPE) cable (Securos, Charlton, Mass) has been tested in an in vitro model for the repair of proximal sesamoid bone fractures and compared against the commonly used stainless steel cerclage wire (SSCW). The ultimate tensile strength of UHMWPE cable constructs was 34% greater than that of SSCW constructs. Fatigue strength was 2 to 20 times greater for UHMWPE cable constructs than for SSCW constructs. Separation of fragments was 153% less for limbs repaired by the cable construct compared with those repaired by the transfixed cerclage technique.77 These cables may also be beneficial in the use of fetlock breakdown injuries, as a palmar figure-eight tension band.

Another type of cable consists of multiple weaved stainless steel, titanium alloy, or cobalt chromium alloy strands (Synthes, Paoli, Pa). It is available as 1.0- and 1.7-mm-diameter cables, consisting of a central bundle of 19 strands surrounded by eight outer bundles of seven strands each (Fig. 81-33). It is designed to be used with all Synthes stainless steel and titanium plates. Specially designed positioning pins are used in empty plate holes and the cable is threaded through an oblong hole in the pin. Once the cable is tightened, the pin cannot move because it is pressed into the plate hole and therefore confined. A special tensioning device is used to tighten the cable before it is crimped with the help of a cable crimper. Care should be taken to not exceed 50 kg of tension. Applying tension at levels higher than 50 kg may cause the cable to cut through soft or osteopenic bone (which is not a problem in horses). This product is used mainly in human orthopedic surgery in the management of periprosthetic fractures in elderly adults, where other internal fixation devices are not successful.78 Additionally, it is used in the tension-band function in the management of patellar fractures and olecranon osteotomies. Indications for these cables are similar to those for the UHMWPE cables in horses.
PINS

Steinmann pins

Steinmann pins are not frequently used in fracture treatment in horses, mainly because they do not provide stability. They are used as transfixation pins in conjunction with external coaptation (see earlier discussion).

Intramedullar application of Steinmann pins is used only in humeral fractures in foals. Multiple pins are introduced parallel to each other to fill the entire medullary space at its isthmus at the distal third of the bone. This "stacked pin" method is presently the treatment of choice in these fractures. For additional stability, these pins may be encircled by cerclage wires and placed into the medullary cavity, possibly through a cortical defect or a drill hole. The wires are subsequently tightened. In cases with a cortical defect, the cerclage may also be applied intramedullarily. The advantage of the stacked pin method is an increase in rotational and bending stability. A single pin provides no rotational stability. Collapse of the fracture along the single pin is a frequent complication.

Application of multiple pins across a capital femoral physeal fracture has been advocated and has met with some success. Steinmann pins have also been used in the treatment of olecranon fractures in the very young foal in combination with a tension band made of multiple cerclage wires.

Rush pins

The Rush pin method of fracture treatment was popular before bone plating was introduced. Fracture fixation using these devices is an art. The slightly pre-bent pins are introduced obliquely into the distal fragment and advanced toward the opposite cortex. The tip, which is flattened on one side, slides off the opposite cortex and is redirected toward the cis-cortex. The pin length has to allow the tips to engage in the cis-cortex both proximally and distally to the fracture, providing four-point contact. Usually, two pins are introduced, one from each side of the bone. When performed correctly, rotational stability is achieved with a minimum of implants and surgical trauma. The Rush pin fixation technique is not applicable to comminuted or open fractures.

NAILS

Intramedullary nails have a place in equine long bone fracture repair, but the ideal implant has not been developed despite recent efforts. Initially, intramedullary nails manufactured for human application were tried in equine fractures with mixed success. For example, in two reports, a solid titanium nail was inserted through the middle carpal joint after removing the articular cartilage of the middle carpal and carpometacarpal joints. The joints were fused to facilitate solid fixation. Transfixation was achieved with 4.5-mm screws inserted through the proximal aspect of the nail. Although good results were achieved, the fact that the joints had to be fused to facilitate healing of MCIII was undesirable. Healing of these fractures can be achieved with plating techniques without fusing a joint.

A system of intramedullary interlocking nails (IIN) has been developed for equine humeral and femoral fractures (Fig. 81-34). Comparison of this method of fracture repair to fracture plating have been met with mixed results in experimental studies. A cadaveric in vitro biomechanical study on immature equine femurs revealed that a diaphyseal osteotomy fixed with two DCPs at 90 degrees relative to each other provided superior strength and stiffness compared with an IIN and a construct of an IIN and cranially applied DCP. In another in vitro study on osteotomized tibias, a construct composed of a 16-mm stainless steel nail with a...
wall thickness of 4 mm and four 8-mm interlocking screws was compared with a human interlocking nail (IIN, Synthes Inc., Solothurn, Switzerland) and to tibias treated by means of double plating.

The interlocking nails achieved similar loads until failure, but the plates demonstrated higher yield loads. Recent in vitro cadaveric studies tested several interlocking nail configurations in MCIII and femora in foals, and femora in adult horses. All constructs were weaker than the intact bone, and the parallel alignment of the holes for the interlocking screws were stronger than the offset screws. One study compared IIN with a combination of an IIN and a DCP, and with two DCPs in a 1-cm gap model in foals, showing the double-plating construct to be closest to the intact bone in most aspects, followed by the combination and the IIN alone.

Several application principles have been advocated in foals for the presently used equine IIN. The location and configuration of the fracture significantly affects the ultimate outcome of the repair. If possible, three interlocking screws should be inserted on either side of the fracture. Fractures near the epiphysis are less readily stabilized with an IIN, and the epiphyseal segment is at an increased risk for secondary fracture through the interlocking screw holes. In these instances, some type of supplemental fixation is desirable to decrease the potential of catastrophic failure of the fixation. In long oblique fractures, the IIN should be positioned to allow one or two interlocking screws placed in lag fashion across the fracture plane, if possible. In a nail–plate construct, the plate is applied 90 degrees relative to the interlocking screws. Whenever possible, bicortical screws are inserted through the plate.

A lateral approach is used to expose the fractured humerus and femur. Prior to reduction, the fracture is debrided and the medullary cavity of the distal fragment reamed. Reaming is accomplished with rigid reamers of increasing size to arrive at an ultimate hole diameter of 13 mm. This procedure destroys the intramedullary blood supply and slows healing. Unreamed intramedullary interlocking nails have not been successfully applied in living horses. Additional exposure is usually necessary to provide access to the proximal end of the bone for normograde reaming of the proximal segment. After both fragments are reamed, the fracture is reduced and held in that position with bone clamps. An appropriate-length nail is chosen, and with the targeting jig attached, the nail is inserted into the reamed medullary canal. Washers are used to prevent the conical heads of the cortex screws from penetrating the cortical bone. A successful result was achieved with an IIN in five of 10 foals with humerus fractures; the foals ranged in weight from 136 to 204 kg. They attained athletic soundness and performed their intended purpose without complications. Three out of three neonates with femoral fractures were treated with IIN fixation. Four out of six older foals with short oblique femur fractures also were successfully treated in this manner. In these foals, a DCP was applied to the cranial aspect of the bone in addition to an IIN.

AFTERCARE
After fracture fixation with any of the internal fixation devices and techniques described here, overlying soft tissues and skin are closed in routine fashion. Application of continuous suture patterns is advocated to reduce surgery time. Depending on the type of fixation and the technique of recovery from anesthesia, application of some type of external coaptation may be considered, because the animal has to be able to get up and place weight on the limb immediately after surgery. If a pool recovery is implemented, the limb and skin incision is in most cases protected only by a plastic adhesive sheet (Ioban 2, 3M Health Care, St. Paul, Minn) after applying cyanoacrylate Superglue to the skin incision. This sheet is covered with elastic adhesive tape (Elasticon, 3M Health Care), which is exchanged for a regular bandage or splint bandage after successful recovery from anesthesia (see Chapters 18 and 22).

External coaptation may consist of a fiberglass cast or a heavy splint bandage (see Chapter 18). Depending on the type of fixation, external coaptation is maintained for a few days to weeks. A fiberglass cast can be applied over a bandaged limb, and after the cast has cured, it can be split in half along the frontal plane. These “half shells” are reapplied using nonelastic adhesive tape. Such coaptation allows evaluation and, if necessary, wound management of the limb underneath. The unaffected contralateral limb should be protected and supported by a pressure bandage. In young foals, too much support is to be avoided to prevent temporary weakness of the flexor tendons. It is important to keep the patient comfortable with the help of moderate amounts of anti-inflammatory and analgesic drugs. These drugs should be used judiciously to prevent toxic reactions and to allow some residual amount of pain, so the patient will protect the injured limb. If a nonweightbearing lameness lasts for a prolonged period, other problems develop in the healthy limbs.

Application of a frog pad in adult horses may prevent the development of laminitis in the contralateral foot. Laminitis is the major complication that occurs after fracture repair. Again, administration of anti-inflammatory drugs in moderate amounts may prevent this problem. As early as possible, the animals should be allowed to walk. Although controlled exercise is advocated, free pasture exercise is discouraged. This is especially important if a weight-bearing fixation was performed and the animal is not placed in an external coaptation device. Patients with casts should not be exercised at all.

Implant Removal
Implants are foreign bodies and may have to be removed, particularly in young athletes. Therefore, implant removal depends on the use of the horse, the type of fracture treated, the type of implants employed, and the potential development of complications, including postoperative infection. Lag screws are not removed in horses unless they produce pain or bone reactions. Recently, the practice of removing lag screws in young racehorses has gained popularity. Frequently, the reason for implant removal is a request by the owner. Cerclage wire used for fracture fixation does not need to be removed unless the wire breaks, as it does frequently in the treatment of transverse fractures of the proximal sesamoid bones. Plates applied to long bones of horses should be removed in most cases. This is especially important if the animal enters or resumes an athletic career. Implants applied to the femur or olecranon and for
arthrodesis purposes are left in place. This presupposes that no problems are encountered with the implants.

When to remove implants after the fracture has healed depends on the age of the animal, the type of fracture treated, and the implants used. In a condylar or stress fracture of MCIII/MTIII, screws may be removed about 2 months postoperatively. Plate removal in foals may be carried out at an average of 4 to 6 months after fracture treatment. Staggered removal of the implants is advocated if two plates were applied, because it reduces the risk of refracturing the bone through one of the screw holes. (Filling the empty screw holes in the bone with a bone graft has been recommended in humans.64)

An important reason for implant removal is infection surrounding the implants. An infection, once established around implants, persists and does not resolve until after the implants have been removed, even in the presence of broad-spectrum antimicrobials.29 Fractures can heal in the presence of infection if rigid internal fixation is maintained. However, it is frequently a race between loosening of the implants caused by the infection, and healing of the fracture. Once an infected fracture is healed, the implants are removed to allow resolution of the infection. If the implants are removed too early, before adequate healing of the fracture has occurred, refracture of the bone is likely. In one case, however, where titanium implants were applied to a comminuted open fracture of the proximal MTIII in a Thoroughbred foal, a postoperative infection resolved completely prior to implant removal (Fig. 81-35).

Figure 81-35. A 2-month-old Thoroughbred colt was admitted with a comminuted fracture of MTIII. A, The fracture was treated with two PC-Fix plates applied over the periosteum. B, This prevented adequate visualization and resulted in suboptimal fracture reduction. An infection developed, which was managed with parenteral broad-spectrum antibiotics, daily flushing of the surgical site, and local antibiotic application. Within a month, the infection had resolved. C, Bacterial cultures taken at the time of implant removal revealed no growth. The foal developed into a successful racehorse.
REFERENCES

Biologic bone grafts are distinguished from synthetic bone replacements because they come from different sources and require a variety of pretreatments.\(^1\)\(^-\)\(^3\) However, the mechanism by which both are integrated into host bone is similar. All grafts are eventually replaced with host tissue by a process called creeping substitution.\(^1\)\(^-\)\(^3\) Mesenchymal stem cells or osteoprogenitor cells and capillary sprouts from either adjacent bone marrow, periosteum, endosteum, or surrounding soft tissues grow into the porous structure of the grafts. There, stimulated by various local substances, they differentiate into osteoblasts, producing new mineralized osteoid that is deposited either on the old matrix or on the synthetic ceramic structure. Osteoclasts are recruited from the vascular system, and they differentiate for later physiologic remodeling to mature lamellar bone.\(^1\)\(^,\)\(^3\)\(^-\)\(^4\) Pretreatment of allogeneic or xenogeneic bone grafts is necessary to reduce antigenicity that could lead to graft rejection.\(^1\)

TYPES AND DEFINITIONS

A distinction is made between fresh biologic bone grafts and preserved ones. A bone graft may be transferred immediately from the donor to the implant site, in which case it is a fresh graft. Preserved grafts include specially prepared pieces of dead bone—for example, decalcified, freeze-dried, irradiated, or sterilized bone. In a third category are artificial bone replacements, which consist of ceramics such as tricalcium phosphate (TCP) or hydroxyapatite (HA).\(^5\) (see Chapter 9).

Bone grafts can be classified according to their origin. A graft harvested from one site and applied to another in the same individual is an autograft. An allograft refers to tissue removed from one individual and given to a genetically different individual in the same species. Tissue transferred between two members of different species is a xenograft. If the transferred tissues are applied in an anatomically similar location, the graft is an orthotopic graft; if the implantation site is dissimilar, the graft is referred to as a heterotopic. Bone grafts may be composed of purely cancellous or cortical bone, or they may be composed of a combination—for example, a corticocancellous graft or, in combination with articular cartilage, an osteochondral graft. In equine orthopedic surgery, fresh bone grafts are always autografts. The most frequently used fresh grafts are autogenous cancellous bone grafts, but cortical chips taken from the fracture site, free cortical grafts, and vascularized cortical bone grafts may be used. Free cortical grafts depend on the ingrowth of host vessels for their nutrition, whereas vascularized cortical bone grafts are harvested with their blood vessels to be anastomosed to the local blood supply.

Preserved grafts are pretreated with either freezing alone, freeze-drying, radiation, sterilization, or complete or surface decalcification.\(^1\)\(^,\)\(^6\) The process of pretreatment kills viable bone cells, reducing antigenicity considerably, and allows safe and sterile storage of the bone grafts. These grafts are kept in bone banks, which makes them easily available on request.\(^6\)\(^,\)\(^7\) Their ease of accessibility avoids a second surgery to harvest the autografts and thus decreases surgery time.

Bone grafts are used most often to facilitate healing after long bone fracture repair, arthrodeses, and comminuted phalangeal fractures in the horse, and autogenous cancellous bone grafts are the most frequently applied type.\(^8\) Therefore, the major emphasis in this chapter is on this technique. Bone banking is discussed for the sake of completeness. In humans and small animals, a variety of bone grafts are used, most of which are not readily applicable to the horse.

**BONE GRAFTS**

**Functions**

Depending on the type of bone grafts, their main function is osteoinduction or osteoconduction.\(^1\) Osteoinduction refers to the local triggering of osteogenesis (new bone formation), whereas in osteoconduction, the matrix of the graft acts as a scaffold into which mesenchymal cells grow.\(^9\)

In fresh, autogenous grafts, osteogenesis occurs partially as the result of the activity of viable osteoblasts aligned on the surface of the living bone graft. Therefore, the greater the surface is, the more living cells are available and the greater is the osteogenic activity that is observed. However, up to 90% of living cells die after bone graft transfer, with only the surface cells surviving. Therefore, the greater the number of surface cells transferred, the larger is the number of osteogenic cells that survive in the graft bed. Therefore, loosely arranged cancellous bone grafts are the most desirable in the horse. The number of surviving cells is also influenced by the handling of a graft during surgery, where dehydration and compacting of the graft are to be avoided.\(^1\)

Some systemic influences and local factors, such as local and systemic cytokines, inflammatory mediators, and growth factors, are very important for the mechanism of osteoinduction.\(^5\)\(^-\)\(^8\) Cytokines are polypeptide molecules capable of signal transduction in cells through specific surface cell receptors. Inflammatory mediators elicit changes in cell metabolism through activating either cyclic guanylate cyclase (cGMP) or cyclic adenosine monophosphate (cAMP).\(^9\)\(^,\)\(^12\) Cytokines, such as interleukins and tumor necrosis factors, and inflammatory mediators, such as nitric oxide and prostaglandin E\(_2\), may be produced either by local mesenchymal, fibrous, or vascular tissue cells. On one hand, these signals attract and recruit undifferentiated mesenchymal cells from the environment to the local area; on the other hand, they also induce bone resorption, facilitating bone graft replacement (creeping substitution). Through the locally invading cells and ongoing bone matrix resorption, a myriad of local growth factors are released that allow the mesenchymal cells to proliferate and differentiate. Through various cell generations, the graft undergoes enchondral ossification into woven bone. This bone is replaced later.
with mature lamellar bone. Growth factors (GFs) involved in fracture healing and graft incorporation are platelet-derived GF (PDGF), fibroblast GF (FGF), insulin GF (IGF), transforming GF (TGF), and the bone morphogenetic proteins (BMP), including osteogenic proteins (OPs).9 The BMPs and OPs belong to the TGF-β super family.11 Various BMPs are now produced synthetically by recombinant processes with molecular biology technologies.

Support, another important function of bone grafts, is mainly derived from corticocancellous or osteochondral bone grafts. These grafts may be transferred as fresh autogenous, vascularized grafts or as allografts. With allogeneous cortical grafts, there are fewer surviving cells than with cancellous bone grafts, and nutrition depends on the formation of new haversian and Volkmann's canals and canaliculi, which means it is a slow remodeling process that may take longer than 1 year, depending on the size of the graft.12 This type of bone grafting is not very important in fracture repair in horses.

The successful incorporation of a bone graft depends on the interplay of the following six parameters: (1) the host bed, (2) the viability of the bone graft, (3) the volume of bone to be grafted, (4) the growth factor activity of the host bed, (5) the metabolic activity index (MAI), and (6) the homostuctural function of the bone graft.

The condition and location of the host bed determines the response to osteoprogenitor cells and perivascular connective tissue. Different bones exhibit different fracture healing rates, depending on local blood flow and bone marrow activity. The more viable and uncompromised the host bed, the better the acceptance of the bone graft.

The better the viability of the bone graft is, the better the acceptance of the graft. Therefore, cancellous and vascularized corticocancellous or cortical bone grafts may have the greatest chance of acceptance.

The larger the volume of bone to be grafted, the longer it takes to become completely incorporated into and remodelled by the host tissue. The longer the time needed for complete incorporation, the greater is the likelihood for development of complications. In large defects, there is a greater need for incorporation of a bone graft with a large surface, such as a cancellous graft. Such a graft demands absolutely rigid internal fixation until structural rigidity is achieved.

Growth factor activity of the host bed and bone graft induces proliferation of perivascular connective tissue, facilitating osteogenesis. Augmentation of the bone graft can be achieved by GFs through recruitment of additional cell populations as well.

The MAI, which is composed of parameters such as heart rate, blood flow, basic metabolic rate, respiratory rate, and body temperature, is correlated with the capacity to incorporate bone grafts, repair fractures, and respond to local growth factors.7 The MAI of humans is 1.0, which is close to the MAI of the dog (1.5). The MAI of the horse has not yet been determined. The closer the MAI of two species, the better is the correlation of the factors influencing bone healing and the more meaningful are comparative studies conducted between them.

The homostuctural function of a bone graft, such as “spacer” function or support function, together with the fixation technique, influences the incorporation of the graft considerably. It may take years until it is completely incorporated or rejected.10

Surgical Techniques

**Fresh Bone Grafts**

**GENERAL GUIDELINES**

It is advisable to use a separate surgical team for harvesting the cancellous bone graft and to plan it in such a way as to allow its immediate embedding into the recipient site by the surgeons repairing the fracture.14 If there is any time lag between harvesting and implantation, the graft should be stored in blood-soaked sponges. It has been shown that the exposure to air or to saline-soaked sponges is harmful to the survival of cells.15 Additionally, exposure of the bone graft to antibiotics before and during harvesting is also detrimental to survival of the cells.15 The bone graft should be lightly packed into the host site (Fig. 82-1). Excessive packing should be avoided to allow the host tissues and fluids ingress to nourish the graft. The graft should be exposed as much as possible to bone marrow and endosteum of the parent portion of the bone.1 It is of paramount importance to ensure rigid internal fixation of the fracture in the presence of a bone graft to allow adequate ingrowth of a healthy vasculature. Otherwise, the cells in the bone graft may not survive, as a result of the lack of oxygen, compounded by mechanical damage.14 Absolute asepsis is a prerequisite for successful application of a bone graft.

**LOCATIONS**

The principal donor sites for cancellous bone grafts in the horse include the tuber coxae (Fig. 82-2, A), the sternum (see Fig. 82-2, B), and the medial aspect of the tibia (see Fig. 82-2, C). All these sites are easily accessible, and large amounts of (viable) cancellous bone may be harvested.16 There is little danger of a fracture through a cortex portal in the proximal tibia, provided the holes are appropriately located.17 Cancellous bone samples from these conventional donor sites were evaluated for the presence of osteoprogenitor cells to those taken from the fourth cocygeal vertebra and tibial periosteum.18 Sternal and tibial bone yielded viable osteogenic cells from 25% and 50% of horses, respectively, whereas yields from tuber coxae, cocygeal

**Figure 82-1.** A cancellous bone graft placed in a bone defect of the skull.
vertebra, and periosteum were 75%, 100%, and 100%, respectively. Tuber coxae and tibial periosteum had significantly greater numbers of osteoprogenitors compared with the fourth coccygeal vertebra. Although a recent study proposed the proximal humerus as an additional graft site, it is not recommended as a viable option.

**Tuber coxae**
A straight 3-cm skin incision should be made over the tuber coxae, through the fat pad and subcutaneous tissues to the bone (see Fig. 82-2, A). Using a 5.5-mm drill bit passed through the 5.5-mm drill guide, a hole is prepared across the thin cortex. With the help of a curet, the cancellous bone located within the ilium is harvested in the quantity needed. Care is taken to avoid breaking through the thin inner cortex of the ilium, which could cause complications. If needed, additional holes may be drilled adjacent to the first one at a different angle. The fat and subcutaneous tissues are closed over the bone in a simple-continuous pattern; an interrupted tension-relieving pattern is used in the skin. In selected cases, stapling of the skin may also be used. A stent bandage, consisting of a gauze sponge rolled up tightly and placed in a longitudinal direction, is sutured over the incision. This bandage protects the skin edges and reduces undue movement in this region, facilitating skin healing. It might be advisable to cover this area with additional padding, especially during the recovery phase and in horses with a tendency to rest in a recumbent position.

Recently, a bone graft–harvesting drill (Fig. 82-3) was introduced (Institute Straumann, Waldenburg, Switzerland). With this device, 4-mm-diameter cancellous bone plugs can be harvested through a stab incision (Fig. 82-4). These plugs are an ideal size when implanted into drill holes of the same diameter during arthrodesis of the distal intertarsal joint (see Chapter 99).

**Sternum**
The sternum is an especially advantageous donor site, because, when the animal is placed in dorsal recumbency, access is easy for the harvesting (see Fig. 82-2, B). The sternum may also be approached with the animal in lateral recumbency; however, this is somewhat more cumbersome and the surgeon may have to perform the surgery in a less desirable position. Fracture treatment in a forelimb using internal fixation augmented by an autograft of cancellous bone from the sternum would be difficult to perform with two surgical teams working simultaneously, because of the proximity of the two surgical incisions. A straight incision is made on the midline until the sternum is encountered. The hyaline cartilage is split longitudinally with the scalpel, and with the help of a periosteal elevator, the sternebrae are identified. The cancellous bone graft is harvested from each sternebra that is isolated. Care is taken not to incorporate hyaline cartilage within the bone chips. If more cancellous bone is needed than is contained within one of the sternebrae, the next nucleus may also be excavated and used as a graft. There are six to seven usable nuclei within the sternum, allowing an adequate amount of high-quality cancellous bone graft to be harvested for any type of fracture. Closure consists of an initial simple-continuous layer along the border of the cartilage, through which the two cartilage flaps are united, followed by routine closure of the sub-
cutaneous tissues and skin. It may be advisable to install a suction or Penrose drain for 24 hours. Additionally, the skin incision should be protected with a stent bandage; because otherwise this region is very difficult to protect.

**Proximal tibia**
A straight incision is made over the medial aspect of the proximal tibia through skin, subcutaneous tissues, and periosteum (see Fig. 82-2, C). Using a 5.5-mm drill bit, the cortex is penetrated in one or two places, depending on the amount of cancellous bone graft needed. In a recently reported technique, two holes were drilled next to each other so that they became one hole 8 to 9 mm long. This allowed access of a rather large curet, and a large amount of high quality cancellous bone graft could be harvested. Closure of the incision is routine. Again, a stent bandage is applied over the incision to stabilize the skin edges.

**Proximal humerus**
The quantity of cancellous bone collected from the proximal humerus with traditional harvesting instruments is comparable to that collected from other sites in horses. The procedure is associated with minimal postoperative incisional complications or lameness. However, because one horse suffered a catastrophic humerus fracture, further research is required to assess the effects of this procedure on humeral breaking strength. On the basis of the risk of catastrophic fracture, this technique cannot be recommended for use in clinical cases, especially if an unassisted recovery from general anesthesia is planned.

**Bone Banking**
**CORTICAL BONE**
Cortical bone banks have never been very popular in equine surgery. Nevertheless, it is possible, and in selected instances even desirable, to develop a bank for certain horse bones. Donor horses should be free of any systemic disease, and the grafts should be harvested using aseptic technique. Donor horses should be free of any systemic disease, and even desirable, to develop a bank for certain horse bones. Harvesting of the grafts is performed after the animal is euthanized, and the grafts should be harvested using aseptic technique. with antibiotics can be used to combat infection locally (see Chapter 88).

Traditionally, nonresorbable chains of polymethylmethacrylate (PMMA) beads are used in combination with antibiotics. When implanted, the antibiotic is gradually eluted over variable time periods. Gentamicin, amikacin, and cephalosporins have been proven to be effective in this manner.25

TCP impregnated with gentamicin is being evaluated as bone replacement for contaminated or infected areas. Use of this product in open fractures in the horse has had promising results. The gentamicin is released over a period of 90 days.26 Gentamicin-impregnated TCP granules were inserted into the medullary cavity immediately prior to final reduction of the fracture. Newer compositions with liquid, resorbable bone cement mixed with gentamicin and TCP are still under investigation. The resorbable bone replacements or cements impregnated with antibiotics have an advantage in that they do not require a second procedure for removal but will be eventually replaced by normal bone tissue.26,27

**BONE REPLACEMENTS USING THE BIOTECHNOLOGY APPROACH**

In recent years, major advances have been made in the field of biotechnology.28,29 In contrast to using synthetic bone replacements alone (Fig. 82-6), biotechnology has allowed the combination of a carrier or scaffold material either with
incubated with mesenchymal stem cells.38,39 or periosteal cells.40

Bioreactors have been developed, where composites are being used in clinical applications in human patients.35-37 especially in large bony defects.

A gel-like matrix or with additional bone-enhancing substances30-33 (Fig. 82-7). Polymers alone or as composites with ceramic substances have had impressive results and are being used in clinical applications in human patients.35-37 Additionally, the use of mesenchymal stem cells in addition to the material composites are being advocated and used in experimental and a few clinical applications.38 Various kinds of bioreactors have been developed, where composites are incubated with mesenchymal stem38,39 or periosteal cells.40 Furthermore, modern diagnostic imaging procedures and the modern polymers allow rapid prototyping of materials prior to surgery with or without additional incubation of stem cells. Finally, modern purification processes have revived one of the oldest surgical materials—namely, silk41—so that it no longer causes inflammatory tissue reactions and can be customized in its structure to local requirements of bone architecture.5,40

Although some of these materials may be too expensive to be used in veterinary surgery at the moment, others are already being applied in clinical trials in horses and will be on the veterinary market in the near future. Composite materials that release bone-enhancing factors in small concentrations over a protracted period of time will be superior to simple bone replacements, enhancing bone healing, especially in large bony defects.

CHAPTER 83

Synovial Joint Biology and Pathobiology
David D. Frisbie

The function of synovial joints depends on the integrity of normal anatomy and cellular function of each of its components. Bone, articular cartilage, synovial fluid, synovial membrane, fibrous joint capsule, and ligamentous structures make up these components (Fig. 83-1). On either side of a synovial joint, subchondral bone is coated by articular cartilage, providing the nearly frictionless contact surfaces of the joint. Synovial membrane and ligamentous joint capsule surround the cartilage and attach to bone on either side of the joint, providing stability and a reservoir for the synovial fluid. The synovial joint is further stabilized by ligamentous and muscular structures that surround the joint; these structures are extracapsular in most instances. Three different classifications of joints exist: synarthroses (immovable), amphiarthroses (slightly movable), and diarthrodial (movable). Diarthrodial joints account for the greatest

number in the body and will be the focus of this chapter. The articulations of diarthrodial joints provide for movement of the rigid skeleton. A healthy joint provides a frictionless system with efficiency that is an order of magnitude superior to the best bearing surfaces known to modern engineering. When pathologic states arise, it is usually because of dysfunction of one or more components. Because the health of the synovial joint depends on the sum of its parts to be working in unison, it is often referred to as an organ system, as all components must be functional for the health of the “organ.” This chapter will explore in more detail each component of the synovial joint both in health and disease.

ANATOMY OF SYNOVIAL JOINTS

Synovial Membrane and Synovial Fluid

The synovial membrane, or synovium, lines the joint cavity and is made up of two layers: intimal and subintimal. The intimal layer is largely responsible for the content of the synovial fluid, is typically one to four cell layers thick, and does not have a basement membrane. The lack of basement membrane is relevant with respect to the role the synovium plays in determining the content of the synovial fluid in the joint and will be covered in more detail later. The subintimal layer is made up of fibrous, areolar, and fatty tissues. A very good blood supply is present in the subintimal tissue, as well as innervation originating from both peripheral and muscular nerve branches (Fig. 83-2). In fact, using an arthroscope close up and focused directly on normal synovial membrane, one can see individual red blood cells coursing through the capillary network of the villi. When viewed both grossly and arthroscopically, the synovium has areas that are flat intermixed with areas of loose collections of villi. These areas of villi are often described as “seaweed-like” when viewed arthroscopically in a fluid medium. The two appearances of the synovium are thought to be related to biomechanical characteristics of the joint area, since they remain relatively unchanged throughout the life of healthy joints.

The cellular population of the intimal layer is based on two basic functions: phagocytosis and protein secretion. The cell types have historically been classified as type A or B synoviocytes on the basis of ultrastructure and immunohistologic characteristics. Cells engaged in phagocytosis or pinocytosis are termed type A synoviocytes, while those responsible for protein secretion have been referred to as type B. More recently, the description of type C cells has been reported, and these cells are thought to represent a cell type between type A and B. Because type A and B cells have demonstrated functions assigned to the other cell type, and because synoviocytes have been shown to be dynamic, it is likely that type C cells represent synoviocytes in a transition from type A to B, or vice versa.

When the focus is on the function of the intimal layer of synoviocytes, the importance of its role in both health and disease of the joint becomes apparent. One function is phagocytosis—the mechanism whereby unwanted particles can be cleared from the joint. However, a central role of the synoviocytes is the secretion of proteins that contribute to both the anabolic and the catabolic metabolism of the joint as a whole. Like many other metabolic processes, when checks and balances are in place, these metabolic processes are part of normal turnover, but when unregulated or aberrant regulation occurs, these same processes can lead to the development of disease. The synoviocytes are responsible for the secretion of a diverse array of proteins that contribute to the synovial membrane proper, as well as to the composition of the synovial fluid, and they include hyaluronan, collagen, lubricin, matrix pro-metalloproteinases (pro-MMPs), interleukins, and eicosanoids (e.g., prostaglandin E<sub>2</sub>). The breadth of these proteins in the pathophysiology of the joint underscores the importance of this tissue.

Another important role of the synovial membrane is to regulate the composition of synovial fluid. Synovial fluid is often referred to as an ultrafiltrate of the plasma. This term implies a more passive process, but is actually very dynamic and inter-related with many factors, including the molecules composing synovial fluid (e.g., hyaluronan size and concentration), degree of inflammation, and lymphatic drainage. Components of the plasma, such as glucose, oxygen, carbon dioxide, and proteins, typically less than 10 kDa in size, are allowed through the endothelium of the subintima and contribute to the composition of the synovial fluid, whereas large molecules are excluded. Routine cytologic examination techniques, as well as normal and disease state levels of the constituents, will be reported later. Most laboratories consider levels of less than 500 cells per deciliter of synovial fluid normal.

Molecules such as hyaluronan and lubricin are contributed to the synovial fluid directly by the synoviocytes. These molecules are thought to be important in the steric exclusion of larger molecules from the synovial cavity, thus regulating synovial fluid composition (Fig. 83-3), and as boundary lubrication of the joint surfaces. The regulation of size and concentration of hyaluronan within the synovial fluid is unknown, but these two factors do affect the functional properties assigned to the molecule. A variety of methods have been used to determine both the concentration and the molecular weight (or size) of hyaluronan.

Figure 83-2. Photomicrograph of a 5-µm section of normal synovial membrane (H&E). A, the intimal layer; B, the subintimal layer; C, a vessel in the subintima.
The diversity of methods has provided a wide range of normal values, 0.33 to 1.5 mg/mL and several thousand kilodaltons, respectively.\(^7,9\) The half-life of endogenous hyaluronan has been estimated by injecting radiolabeled hyaluronan into the joint and tracking both its degradation and its clearance. It appears that the majority of exogenous hyaluronan is cleared within 48 hours through the synovium and lymphatics, with degradation occurring in the joint space through steric hindrance. (Adapted from Howard RD, McIlwraith CW: Hyaluronan and its use in the treatment of equine joint disease. In McIlwraith CW, Trotter GW, editors: Joint Disease in the Horse, Philadelphia, 1996, WB Saunders.)

Periarticular Ligaments and Joint Capsule

Periarticular ligaments, the fibrous joint capsule, and surrounding muscles provide stability to synovial joints. The contribution to stability afforded by each of these structures differs according to its anatomic location. Joints higher in the limb obtain more stability from muscle than those lower in the limb, so the contour of the joint surface and stability from the joint capsule are more important in the lower limb, although muscular stabilization is a factor. The role of muscular stabilization cannot be overemphasized. For example, even with all periarticular ligaments and the joint capsule intact, desensitization of the suprascapular nerve results in the innervation of a joint is seen in association with perivascular structures.\(^6\) The attachment of these structures to bone has been compared to Sharpey's fibers, because the collagen fibers course through both fibrocartilage and calcified cartilage prior to their insertion in bone. This type of transition is credited with the biomechanical pullout properties (the amount of force needed to pull a ligament from the bone attachment) of the ligaments and joint capsule.\(^1\) It is important to note that these tissues are metabolically active and undergo hypertrophy with activity and atrophy with immobilization. Immobilization has been shown to affect the microscopic, enzymatic, and biomechanical properties of ligaments, suggesting that immobilization should be used temporarily to maintain joint stability during a controlled return to use after injury, as is used in human medicine in the form of function splints (knee braces).\(^14\)

Subchondral Bone

The subchondral bone plate, along with epiphyseal bone, provides contour and stability to the articular cartilage. The subchondral bone plate consists of cortical bone with the haversian system running parallel to the joint surface, unlike the diaphyseal cortical bone, where the haversian system runs perpendicular to joint surface. The biochemical and histologic appearance of subchondral bone is similar to bone in other locations. In humans, the subchondral bone plate has been shown to be approximately 10 times more deformable than the cortical shaft.\(^10\) Remodeling or stiffening of the subchondral bone plate has been noted to occur with osteoarthritis in humans and is considered deleterious to the joint function.\(^13\) This has sparked similar exploration in horses, and, although remodeling and sub-
chondral bone sclerosis is easily documented, especially in areas such as the third carpal bone, deleterious changes in proteoglycan content in this location have not been documented to date. However, subchondral bone microcracks and other forms of bone remodeling have been demonstrated in this area in response to exercise, although their relationship to pathophysiology is not well defined. The subchondral bone plate is integral to joint function as a whole; research in this area is quite active and may provide insights into its role in disease.

Articular Cartilage
Articular cartilage is the central structure that constitutes the joint surface and ultimately its function. In conjunction with the synovial fluid, articular cartilage is credited with providing the nearly frictionless movement of the synovial joint. Although other components of the joint, such as the subchondral bone, synovial membrane, joint capsule, and ligamentous structures, are integral for proper function and continued health of the joint, it is the state of the articular cartilage that is typically used to define joint health. Furthermore, although it is likely that disease may start in components of the joint other than the articular cartilage (e.g., subchondral bone or ligamentous structures), the degeneration and slow or poor healing response of the cartilage usually defines the level and progression of the joint disease.

On gross appearance, the articular cartilage appears smooth or glasslike (hence the term hyaline). In most areas, the articular cartilage has an opaque white color, with areas of thin articular cartilage appearing slightly pink because of the underlying subchondral bone color showing through. Although grossly the surface of articular cartilage appears flawless, a scanning electron microscope reveals it to be gently undulating with depressions that appear to correlate with surface chondrocytes. These depressions have been estimated to be 20 to 40 µm in diameter and have a density of about 430/mm². The thickness of articular cartilage varies by joint, location (related to the degree of weight-bearing), and age, but it is in the 1- to 4-mm range.

The lack of vascular, lymphatic, and neural supply makes cartilage a unique tissue and dictates a dependency on diffusion for nutrient supply and waste removal. The nutritional supply is provided via the synovial fluid. The nutritional solutes diffuse from subintimal vessels through the intimal layer of the synovium to the synovial fluid, then through the articular cartilage matrix, until they finally reach the chondrocytes. The ultrastructure of the chondrocytes supports a diffusion gradient; for example, a decrease in the number of mitochondria in deeper chondrocytes suggests that they are less dependent on oxygen than chondrocytes located more superficially.

The chondrocyte content of articular cartilage typically accounts for 1% to 12% of the volume of the cartilage, with the remaining component being termed extracellular matrix. The extracellular matrix is somewhat complex but can be broken down into three main components: collagens, proteoglycans, and water. Water is the most abundant molecule of the extracellular matrix, making up about 70% of the wet weight in adults and closer to 80% in young and immature animals. On a dry weight basis, the extracellular matrix is composed of approximately 50% collagen, 35% proteoglycan, 10% glycoprotein (e.g., growth factors, cartilage oligomeric protein [COMP], proteinases), 3% minerals, 1% lipids, and 1% miscellaneous substances.

Microscopic Appearance
On the basis of the microscopic appearance of both the chondrocytes and collagen orientation, articular cartilage has been historically divided into four contiguous zones (Fig. 83-5):
1. The superficial (tangential) zone has the highest density of chondrocytes. These chondrocytes appear flattened and are oriented with the long axis of the cell parallel with the joint surface. The collagen here is more densely packed than in deeper layers, and the orientation of the fibers is also parallel with the joint surface. Recently, there has been acceptance of a previously described but refuted acellular layer of collagen called the lamina splendens. This layer has fibril diameters that are distinctly different from those of the traditional cellular portion of the superficial zone and that can be consistently separated from the cellular portion of the superficial zone without damage to the collagen network. The lamina splendens is only loosely connected to the fibrous structure in the adjacent layer beneath. It is, however, firmly connected to the deeper cartilage matrix at the vicinity of the synovium, where it undergoes transition to synovial tissue.

2. The intermediate (transitional) zone is characterized by larger, more ovoid to round chondrocytes.

3. The deep (radiate) zone has the largest chondrocytes, and the long axis of the cell is oriented perpendicular to the joint surface.

4. The calcified zone consists of mineralized cells and matrix. The tidemark refers to the junction of the noncalcified and calcified cartilage, which is a distinct transition seen on histologic sections. More recently, the tidemark has also been described arthroscopically.

**Cartilage Collagens**

Collagen is considered the component of articular cartilage that provides the framework or lattice in which all other matrix molecules are constrained. It is also the component attributed to the counteraction of tensile stresses seen at the joint surface. As described previously, the architecture of the collagen differs depending on its zone or depth within the cartilage. In 1925, Benninghoff described an arcade configuration of articular cartilage collagen, which is helpful in understanding the function of the cartilage. Although the overall accuracy of his model has been challenged, it is useful for demonstration purposes (Fig. 83-6). The superficial pattern of the collagen framework was described as “armor plating,” referring to the tough, resilient, skinlike cartilage surface. The collagen content in this area is higher and the fibrils are of smaller diameter (about 31 nm) with an orientation parallel with the joint surface, which is different from collagen in deeper zones. Based on this configuration, minute openings exist in the superficial layer of cartilage, which have been calculated to be around 6 nm in diameter. This pore size would preclude large proteins such as hyaluronan from entering the cartilage from the synovial fluid in any significant quantities. However, small ions and molecules such as glucose could readily pass through an opening of this size. As previously mentioned, the collagen fibrils of the intermediate zone are oriented in a more random pattern and are between 40 and 100 nm in diameter. The collagen fibrils of the deep zone have the largest diameter, are oriented perpendicular to the joint surface, and cross the calcified zone prior to attaching within the subchondral bone. This pattern of collagen orientation is supported by light and electron microscopy, with further confirmation by an interesting phenomenon called the Hultkrantz line, which appears when the articular surface is penetrated with a pin and stained with India ink. The round hole made by the pin appears as an elongated slit, and the axis of the slit has been found to run perpendicular ...
to the collagen fibril orientation and to the maximal surface tensile strains. This method is currently the preferred test to determine the orientation of collagen in articular cartilage (Fig. 83-7).

At least 16 different collagens have been described in mammalian species, and they are divided into two main categories on the basis of their primary structure and supramolecular assembly: fibril-forming collagens (including types I, II, III, V, and XI) and non-fibril-forming collagens. Collagen turnover is much like that of other fibrous connective tissues, but it tends to be slower than that of other matrix components of the articular cartilage. It has been shown that significant collagen synthesis occurs in adult cartilage, although not much is understood about the process by which orientation is controlled in response to remodeling.

**TYPE II COLLAGEN**
The primary collagen of articular cartilage is type II and is produced by the chondrocytes. It constitutes 90% to 95% of the total collagen content. The principal differences between type II and type I collagen (the latter found in the majority of other musculoskeletal tissues) are the number of hydroxylysine molecules and an increase in glycosylation. Type II collagen is a homotrimer composed of three identical collagen molecules that are constructed in such a manner that the start of each molecule is offset from the next by 25%, or by a "quarter stagger" (see Fig. 80-3). Of the other types of collagen found in articular cartilage, types IX and XI are thought to be integral in the organization and mechanical stability of the type II collagen fibrillar network (Fig. 83-8) and are intimately associated with type II collagen.

**MINOR COLLAGENS**
The content of type IX collagen in articular cartilage decreases from being around 10% of the collagen protein in fetal tissue to being about 1% in the adult. This molecule is found on the outer surface of the type I triple helix and is thought to provide a covalent interface between the surface of the type II collagen fibril and other type II fibrils as well as the interfibrillar proteoglycan domain, thus providing mechanical stability of the fibrillar network. Types VI, XII, and XIV collagen also are thought to have roles in the association between fibrillar collagen and other matrix components. Type XI collagen, on the other hand, is found within the type II triple helix and acts as a core filament on which the type II molecules are deposited during formation. Type XI collagen accounts for about 3% of mature collagen protein. Type VI collagen binds both hyaluronan and fibronectin and has been identified in the perilacunar area.

**Proteoglycans**
Proteoglycans make up the other major component of the articular cartilage extracellular matrix, about 35% on a dry weight basis. As the name implies, these molecules are a combination of protein (proteo for the core protein to which glycosaminoglycans are attached) and glycosaminoglycan (glycan for the repeating disaccharide or polysaccharide). At first glance, the nomenclature of proteoglycans appears somewhat complex, but when broken down into its components it is relatively straightforward, and it is important to understand its evolution. The proteoglycan molecule aggrecan makes up about 85% of the proteoglycans that in turn make up the extracellular matrix, and it is mainly responsible for providing the resistance to compressive forces within the articular cartilage. The other proteoglycans are less studied but function in interactions with collagens and in various metabolic roles in cartilage.

**AGGREGAN**
A single (monomer) aggrecan molecule is made up of two main components: the core protein, which acts as the backbone of aggrecan, and the glycosaminoglycans (GAGs) that attach radially to the core protein. The three main GAG molecules (Fig. 83-9) that make up aggrecan are chondroitin-4-sulfate, chondroitin-6-sulfate, and keratan sulfate. Their ratio differs with age. Of note is an increase in chondroitin-6-sulfate over chondroitin-4-sulfate as the cartilage becomes more mature. The GAGs covalently attach to the core...
protein, and about 100 chondroitin sulfate molecules preferentially attach at the carboxy end of the molecule. Likewise, approximately 100 keratan sulfate molecules are preferentially found closer to the N-terminal region of the aggrecan monomer. These regions are sometimes described as chondroitin- or keratan-rich regions. Because of the high negative charge associated with the GAGs, they tend to repel each other (chemical expansive stresses) and attract water, creating positive pressure (Donnan osmotic pressure). The combination of these two forces has been termed cartilage swelling pressure and is roughly the equivalent of tire pressure.

Current research has focused on delineating various functional and structural domains along the core protein. These regions or domains have been shown to help define the breakdown of various catabolic enzymes involved in normal and pathologic processes—for example, the cleavage site of aggrecanase is different from that of stromelysin, two molecules important in aggrecan turnover. Three main domains have been defined: G1, G2, and G3. The G1 region of the core protein interacts with hyaluronan, and this interaction is involved in arranging about 100 aggrecan monomers along a hyaluronan backbone. The G2 region is located on the N-terminal side of the keratan sulfate–rich region and is a key target of enzymes that break down aggrecan. The G3 region is on the “end” or carboxy side of the aggrecan molecule and in fact is present in only some aggrecan molecules, suggesting a less important role.

**Aggrecan (proteoglycan) aggregates**

Aggrecan monomers are further organized into large aggregates around a hyaluronan molecule. These aggregates can be in the range of 200 million daltons in size and comprise over 100 aggrecan monomers. The noncovalent bond between the aggrecan monomers and hyaluronan is stabilized by a small group of link proteins in conjunction with the G1 domain of the core protein (Fig. 83-10).

**SMALL PROTEOGLYCANS**

About 5% of the articular cartilage proteoglycans are termed small proteoglycans or nonaggregating proteoglycans. Like aggrecan, they consist of a protein core and attached glycosaminoglycan chains. As the name implies, these molecules are smaller than aggrecan—in fact, the core protein is about 25% of that found in an aggrecan molecule. Examples are biglycan, decorin, and fibromodulin. Decorin and fibromodulin are found associated with collagen molecules in the superficial zones of the articular cartilage. Decorin has been shown to inhibit type I and II collagen formation, and fibromodulin inhibits fibrillogenesis. Biglycan and decorin have been shown to bind transforming growth factor-beta (TGF-β), thus making it unavailable to perform its biologic function. This may play an important role in the healing process of articular cartilage and needs to be better understood to improve intervention in cartilage healing.

The overall condition of the extracellular matrix is presented graphically in Figure 83-11.

![Figure 83-9](image1)

**Figure 83-9.** An aggrecan monomer consisting of a central core protein (CP) interrupted by three globular domains (G1, G2, and G3). Peripherally on the molecule are the keratan sulfate (KS) and chondroitin sulfate (CS) regions. Proteolytic cleavage of the molecule in vivo first occurs in the interglobular domain (IGD). (From Koopman WJ, editor: Arthritis and Allied Conditions: A Textbook of Rheumatology, vol 1, ed 13, Baltimore, 1997, Williams & Wilkins.)

Chondrocytes
The chondrocytes, as previously mentioned, represent a small proportion of the total volume of the articular cartilage. The morphology and metabolism of the chondrocytes vary according to their depth within the cartilage, and the presence of lacunae represents a microenvironment around the chondrocytes that is more prevalent in the deeper layers. Chondrocytes have cytoplasmic processes that extend into the interterritorial region and appear to sense the biochemical and biomechanical environment, but, unlike the cytoplasmic processes of osteocytes, they do not make contact with cellular processes of other chondrocytes. These cytoplasmic processes may represent one mechanism through which the chondrocytes respond to articular cartilage loading. It appears that at a low level of mechanical stress, chondrocyte metabolism favors the catabolic processes, whereas at normal physiologic levels, anabolic processes are favored, and a balance of metabolism is possible. In contrast, at super-physiologic levels, the metabolism favors catabolism, potentially as a result of an overwhelmed anabolic pathway. Alterations in extracellular matrix pressure caused by biochemical changes may also direct chondrocyte metabolism.

Turnover of the proteoglycan portion of the extracellular matrix occurs faster than the collagen component. Specifically, proteoglycan turnover has been estimated at about 300 days in dogs and rabbits, versus an estimated 350 days for total turnover of the collagen in humans and 120 in dogs. These rates can be upregulated in disease states—in fact, upregulation of anabolism of both aggrecan and collagen synthesis appears to be one of the earliest changes detected in osteoarthritic processes. More detail on cytokines and regulation of articular cartilage metabolism will be covered in subsequent sections.

PHYSIOLOGY OF SYNOVIAL JOINTS

Intra-articular Volume and Pressure
The volume of the synovial space or joint cavity varies with its anatomic location, and, because of the elasticity of the joint capsule, it can change depending on various factors (e.g., disease, level of exercise). As an example, horses exercising at an increased level are often noted to have synovial effusion, notably in the fetlock and tarsocrural joints, without pathology being present. Some data on the “normal” synovial volume have been published, but, as previously noted, this can be somewhat subjective depending on the degree of joint capsule distention that is perceived as typical. The mechanism by which intra-articular volume and pressure are regulated is poorly understood. Most synovial joints are reported as having negative pressure in a neutral position, whereas at the extremes of flexion and extension the intra-articular pressure increases up to 30 psi in the human knee. These pressures are also sensitive to synovial effusion; increased pressures can be translated to the innervation of the joint capsule and subsequently to joint pain during range-of-motion activities.

Joint Mechanics
Joint mechanics are unique and very complex, largely because of the articular cartilage and its response to loading. The study of the loading properties of synovial joints is a very active field whose scope is beyond the reach of this
chapter, but it is summarized here. Joint mechanics are dependent on three aspects: kinematics, kinetics, and joint lubrication. Kinematics involves the study of the motion of the articulating surfaces in relation to each other. Kinetics relates to the forces that are created during the motion of the joint and the loads that are created across the articular surface. Joint lubrication provides a nearly frictionless movement of the soft tissues and articular cartilage.

**Kinematics**

The kinematics of a particular joint are a function of the geometry of the joint surface—specifically, of the articular cartilage and the underlying subchondral bone, as well as the periarticular supporting structures such as ligaments and muscles. The types of motion that occur in joints fall into three categories: translational, rolling, and sliding motions. Translational motion refers to movement without rotation, where two surfaces move past each other. This type of motion somewhat describes the movement in the spine and shoulder. Both rolling and sliding imply some degree of rotational component, which adds another dimension and makes the mathematical models and understanding of these motions complex. Pure rolling motion implies that the instant center of rotation is always at the point of contact between the two surfaces, and that the distance over which contact occurs is similar on both opposing surfaces. In sliding motion, the point of contact is not the instant center of rotation, and the areas of contact during the motion are not equal on both surfaces (Fig. 83-12). Most synovial joints have some component of sliding and translational motion, and pure rolling motion is just theoretical.

Another factor that affects the kinematics of synovial joints is the observation that joint surfaces that are relatively congruent possess thinner articular cartilage than those with incongruent surfaces. Furthermore, in some joints, overall joint congruity appears less when they are unloaded than when they are under load. This is thought to allow better distribution of forces over a larger surface with increasing loads. Fluid-film mechanisms are believed to provide the low friction environment for the articular cartilage at physiologic loads, accomplished by creating a wedge of fluid between the two bearing surfaces. Several models have been proposed, including squeeze film, hydrodynamic, and elastohydrodynamic models (Fig. 83-13). The elastohydrodynamic model, which is accepted as best representing lubrication of the articular cartilage, is based on the attraction of water by aggrecan molecules at the porous articular surface. In this model, when load or pressure is applied to the surface, water is squeezed from the articular surface and interposed between the bearing surfaces. With joint movement, a wedge

---

**Figure 83-12.** The three types of joint motion. (Adapted from Delahay JN: In Wiesel SW, Delahay JN, editors: Principles of Orthopaedic Medicine and Surgery, Philadelphia, 2001, WB Saunders.)
of fluid is created, the leading edge of which is wider and exudes fluid, and at the thinner trailing edge, fluid is thought to be resorbed. Stated another way, as load is applied to the bearing surface of the articular cartilage, fluid is squeezed from the cartilage, separating the surfaces, and is resorbed as the load decreases on the backside of the motion. The material properties responsible for the fluid flow in the articular cartilage have been studied in detail.

Akeson used an analogy of an air tent (like those used to cover tennis courts) as a very effective way to understand the biomechanical function of the articular cartilage as it relates to the components of the cartilage matrix and fluid flow. The components required for the proper function of the air tent are a pump (intake portal and fan), an inflation medium (air), and some form of fabric enabling containment of the inflation medium, thus creating a pressurized system. These tents are engineered to have small openings in the fabric, which require the pump to move more air inward than is escaping to keep the tent inflated. In articular cartilage, the pump corresponds to the proteoglycans; their ability to attract solutes based on their strong negative charge is the driving force of the pump. The inflation medium is solutes from the synovial fluid made up mainly of water, and the containment material, or fabric, is the network of collagen. Instead of entering through a single intake port of a mechanical pump, solutes gain access to the articular cartilage through the fine network of pores formed in the superficial layer of collagen, and likewise these molecules exit via these pores. Both systems (air tent and articular cartilage) depend on all components functioning appropriately and in unison. For example, if a tear in the containment material is too large, the pump cannot continue to pressurize the tent and the system collapses; likewise, if the pump fails, the normal egress of inflation media ultimately ends in a collapse of the tent.

In a state of equilibrium, the articular cartilage maintains a balance of pressure created by the interaction of aggrecan and water that is counteracted by the constraints of the collagen network. When an external load is applied to the articular surface, water flows out of the surface pores until a new equilibrium is reached. This process is relatively complex and not linear in nature. For example, as water egresses out of the articular cartilage as a result of increased surface load, the proteoglycans are forced closer together and generate greater repulsive pressures as they come closer to each other, much like similar poles of magnets repel each other with increasing proximity. Such fluid movement in and out of the articular cartilage is of great interest, because it is integral to the lubrication of the joint surface, load bearing functions of the articular surface, and nutrition of the chondrocytes.

The nutritional supply of the articular cartilage is thought to be provided through the exchange of solutes present in the synovial fluid during loading and unloading of the
articular surface. Maroudas and colleagues calculated that based on this type of supply, the articular cartilage was limited to 6 mm of thickness for chondrocyte viability to be maintained, a calculation that appears to be accurate in terms of synovial joints.35

The term viscoelastic is used to describe the biomechanical properties of articular cartilage, and as the name implies, it is a combination of viscous, or fluid, and elastic biomechanical properties. When a static load is applied in a laboratory setting, there is an initial rapid movement of water out of the cartilage in the fluid phase, followed by a slower loss of water and compression of the collagen known as the creep phase. A time-deformation curve is used to graphically represent the response of the cartilage to loading after the static application of a load (Fig. 83-14). The loss of water and compression of the tissue, forcing the proteoglycans or aggrecans into closer proximity and repelling the forces of the proteoglycans from one another, also contributes to opposing the loading force in the creep phase. It has been estimated that 2- to 4-mm-thick cartilage can take 4 to 16 hours to reach creep equilibrium.36

PATHOPHYSIOLOGY OF OSTEOARTHROPATHY

Osteoarthropathy is a general term defined as any disease of the joints and bones. It is derived from the Greek words osteo ("bone or bones") and arthron ("joint"). A more specific term that relates to disease of the articular cartilage is osteoarthritis, defined as a disorder of movable joints characterized by degeneration and loss of articular cartilage. The suffix itis is somewhat misleading because it suggests a central inflammatory role, which is not present in many joint diseases of both horses and humans. Human rheumatoid arthritis is a notable exception and does have a central inflammatory role. Some definitions of osteoarthritis even state that it is a noninflammatory disease process, which is also somewhat misleading because inflammatory factors do play a part in most arthropathies (defined as any joint disease). Because of these discrepancies, several terms are used to describe similar disease processes. Other common terms are degenerative joint disease (DJD), which circumvents these issues but is often not favored as a scientific term. Osteoarthrosis is also sometimes used, correctly not emphasizing the inflammatory component, but this is defined as a chronic condition, which is not always accurate. Osteoarthrosis is, in the author's experience, the currently accepted term describing degeneration of the equine articular cartilage. Therefore, this term will be used in this chapter.

Many texts define specific mechanisms as being responsible for the pathogenesis of osteoarthritis. For example, Caron describes three proposed mechanisms for osteoarthritis,37 the first being fundamentally defective cartilage with abnormal biomechanical properties. Thus, the cartilage fails under normal loading conditions. An example of abnormal biomechanical properties is the genetic defect described in humans that results in a type II collagen that is unable to withstand normal joint loading.38 The second mechanism involves abnormal change in the subchondral bone. It is accepted that subchondral bone typically undergoes remodeling in response to exercise or to changes in load. It is thought that in some cases, the bone increases its density to a pathologic level, which in turn results in a stiffer or less compliant bone–cartilage unit that is prone to failure. The third proposed mechanism revolves around normal cartilage that is exposed to abnormal forces—for example, those that may be seen with abnormal joint congruity.
resulting from a collateral ligament strain. In this mechanism, abnormal forces overwhelm the normal metabolic repair mechanisms in the articular cartilage and ultimately lead to its failure.

McIlwraith has also outlined discrete mechanisms whereby osteoarthritis may ensue, and many similarities exist. More recently, he gave an example of a scenario that could lead to osteoarthritis and described how the different joint tissues may be involved, but he did not elaborate on previously defined mechanisms. This trend for more general pathogenic descriptions is favored by the author. It is probable that most cases of equine joint disease have some involvement of most joint tissues: subchondral bone, articular cartilage, synovial fluid, synovium, ligamentous joint capsule, and external stabilizers of the joint such as ligaments, tendons, and muscles. This is not to say that specific components do not play a leading role; and initial failure of a single component or tissue is not often the case, but rather each component has some capacity for repair, and clinical disease usually is characterized by involvement of multiple joint tissues in some degree of pathology.

**Metabolism of Arthritic Cartilage**

It is widely accepted that all joint tissues have normal metabolic turnover, and the turnover is a balance of anabolic and catabolic pathways. Osteoarthritis at its origin may be defined by the predominance of the catabolic pathway, which leads to the ultimate failure of the tissue. Two interrelated factors should be considered in the pathogenesis of osteoarthritis: abnormal mechanical loads and metabolic tissue failure. Abnormal mechanical loads may be in the form of mechanical instability that can overwhelm the normal repair process of the tissues it is acting on. It may range from microdamage because of slight imperfections in conformation, to a single traumatic event leading to immediate catastrophic failure. Microdamage is believed to accumulate over time, leading to failure of the tissue after a failed reparative effort, and it may be likened to microcracks in an airplane wing that ultimately lead to failure if not repaired in time. On the other end of the spectrum, immediate damage to the cartilage could occur with a single impact without chance for repair, such as an articular fracture caused by a traumatic event. Metabolic tissue failure revolves around normal tissue metabolism and the fact that all the tissues of the joint have some capability for normal turnover and thus repair. However, some tissues, such as bone, are very adept at repair, whereas others, such as articular cartilage, are less adept. Thus, osteoarthritis could be defined as the point at which the anabolic repair process is overwhelmed by the catabolic processes. As described earlier, the imbalance and failure can be initiated by mechanical forces or by an inherent defect caused by a genetic imperfection, such as a type II collagen defect. A continuum of disease severity and involvement of multiple joint tissues is often the case in osteoarthritis; the etiology is most likely multifactorial, and at some stage, it includes some degree of both abnormal mechanical loads and metabolic tissue failure. The current understanding for normal metabolism and, in the case of osteoarthritis, response to injury for each joint tissue is described in the following paragraphs.

**Mechanisms of Articular Cartilage Matrix Depletion**

**Synovial Membrane and Ligamentous Joint Capsule**

The involvement of the synovial membrane and joint capsule in the pathogenesis of osteoarthritis is often not emphasized, with more focus being on the articular cartilage and bone. The synovium is a very dynamic tissue that has an integral role in influencing the joint environment, especially through the constituents of the synovial fluid, and thus it can have an especially significant effect on the articular cartilage. The highly vascular nature of the synovium allows it to act as the conduit and regulator for inflammatory cells and peripheral mediators that influence metabolic processes, especially in the release of catabolic substances affecting the joint. Likewise, the synoviocytes themselves, much like the chondrocytes, are capable of producing a wide variety of anabolic and catabolic enzymes, including prostaglandins, cytokines, and matrix MMPs. In vitro experiments have shown the importance of mediators released specifically from the synovial membrane in regard to the degradation of articular cartilage. A limitation in determining the relative quantitative and temporal contributions of the synovial membrane to disease in vivo is our inability to identify the origin of the mediators in situ as being synovial or chondrocytic. To avoid redundancy, a more detailed description of the mediators and their role in osteoarthritis will be presented next, under "Chondrocytes."

Primary synovitis or capsulitis is thought to result from biomechanical damage, which may be on a continuum of repetitive trauma from discrete incidents. Severe trauma can lead to an effect on the joint capsule’s role in joint stability and thus joint-wide abnormal biomechanical forces. The response of the joint capsule to injury is to form a fibrous repair tissue that is not biomechanically equivalent to the original tissue and can often result in a decreased range of motion for the particular joint. It is conceivable that this may have long-term ramifications of altered use of the joint and overall abnormal biomechanical forces to the joint tissues. Although the synovium is not thought to have any biomechanical stabilizing properties, it does respond to injury through cellular and enzymatic pathways. It is worth noting that synovitis and capsulitis can be secondary to other abnormalities in the joint. Synovitis may be secondary to other damage within the joint such as occurs with an osteochondral fragment in the carpus. In this example, physical damage to the tissues as well as liberation of debris and mediators from the damaged cartilage and bone will affect the synovial membrane and capsule. In concert with the lymphatic drainage of the joint, the synovial membrane is responsible for clearing debris from the synovial space. Neutrophils, macrophages, and mononuclear cells can also be routinely found in inflamed synovial membrane, contributing to both the phagocytic role of the membrane and the production of enzymatic mediators.

Histologic abnormalities seen in the synovial membrane can be characterized by edema, hyperplasia of the intimal cell lining, hypervascularity, cellular infiltration of inflammatory cells, and fibrosis of the subintima. The order in which these events appear loosely corresponds to the appearance of the abnormalities in an equine model of
osteoarthritis and presumably in naturally occurring disease. Changes documented histologically support alterations seen in other areas of the joint. For example, an increase in vascularity is typically associated with some degree of synovial effusion and an increased protein concentration in the synovial fluid. The increase in protein and fluid is thought to be associated with "gaps or leakiness" of the endothelial cell layer. Although ill defined, alterations in the lymphatic drainage of the synovial space is most likely a component of synovial effusion, with one proposed mechanism being an increased fluid pressure allowing less egress via the lymphatics. Intimal cell hyperplasia is also seen in cases of synovitis and is believed to be associated with a substantial metabolic response by the synoviocytes and most likely contributes to the central pathophysiologic events in osteoarthritis.

**Chondrocytes**

The joint chondrocytes are responsible for maintaining their surrounding environment through a complex interaction of anabolic and catabolic mediators as well as mechanical stimuli. In osteoarthritis, the net outcome favors the catabolic pathways, and degeneration of the articular cartilage ensues with loss of the key matrix components, including aggrecan and type II collagen. There has been a long-raging debate over the definition of the earliest sign of osteoarthritis as it relates to aggrecan or type II collagen loss (reminiscent of the chicken-or-egg argument). Both in vitro and in vivo studies have documented loss of aggrecan as an initial biochemical event. Furthermore, it appears that upregulation of the synthetic pathways is one of the earliest metabolic manifestations, although the net loss of aggrecan and collagen prevail. The quality and quantity of both matrix components are affected, with an increase in water content and surface fibrillation also being early events in articular cartilage degeneration. This, in turn, will affect the mechanical properties of the cartilage, making it less able to withstand normal loads, perpetuating the disease process, and inciting changes in other tissues such as bone and synovial membrane as the cartilage loses its functionality.

The proteolytic enzymes synthesized by the chondrocytes and synoviocytes, and their role in cartilage breakdown, have been extensively studied. They are described by their catalytic mechanisms and include MMPs, aspartic proteinases, cysteine proteinases, and serine proteinases, with the MMPs thought to be most involved in the pathogenesis of osteoarthritis.

**Matrix Metalloproteinases**

The MMPs are grouped together by a requirement for zinc in their active binding site and are typically described either by a descriptive name or by a numerical MMP assignment. To date, 25 different MMPs have been described. The descriptive name is often based on the substrate the MMP was first observed to degrade—such as collagenses, stromelysins, and gelatinases. The MMPs are secreted in an inactive "pro" form and collectively possess the ability to degrade all of the major components in the articular cartilage; thus, they play a major role in both health and disease of the articular cartilage. The synoviocytes and chondrocytes as well as other cell types are capable of MMP production. Increasing concentrations of MMPs have been correlated to areas of histologic abnormalities, signifying their active role in cartilage degradation. The major MMPs that have been incriminated in osteoarthritis include collagenase 1 (MMP-1), collagenase 2 (MMP-8), collagenase 3 (MMP-13), stromelysin 1 (MMP-3), and two gelatinases (MMP-2 and MMP-9). A family of enzymes called "a disintegrin and metalloproteinase" (ADAM) is structurally and functionally related to the MMPs and is also a major factor in aggrecan cleavage. A summary of the nomenclature and function of the MMPs and related proteinases can be found in Table 83-1.

* Expressed by chondrocytes. All are expressed in synovium.
† MMPs characterized in the horse.
‡ MMP-13 expression is relatively weak in equine system.
Interstitial or tissue collagenses (MMP-1) is able to break intact type II collagen molecules by cleaving all three collagen α-chains of the triple helix at a specific amino acid sequence (residues 775-776). Collagenses 2 or human neutrophil collagenase (MMP-8) is released from polymorphonuclear leukocytes (PMNs) and was first shown to be active in human osteoarthritis but has more recently been identified as having activity in equine cartilage. Collagense 3 (MMP-13) has been shown to be more aggressive in type II collagen degradation, cleaving it 10 times faster than MMP-1. Also found in higher concentrations in diseased cartilage of horses and humans, MMP-13 is upregulated by interleukin-1 (IL-1) and tumor necrosis factor (TNF), key enzymes at the top of the articular cartilage catabolic pathway.

Stromelysins have been studied most notably for their ability to break down proteoglycans, but partially degraded collagen and other minor cartilage proteins can be substrates. Much of the credit for breaking down aggrecan in osteoarthritic cartilage has recently been given to members of the ADAMs family of enzymes, specifically aggrecanases. It is currently thought that aggrecanases play a pivotal role in proteoglycan depletion in disease cartilage. The gelatinases also have a diverse range of substrates, including partially degraded collagens and elastins.

**Cytokines**

Historically, the term cytokine denoted small regulatory proteins that were associated with catabolic pathways. More recently, the term has been broadened and is now considered to define catabolic, modulatory, and anabolic proteins that are produced by one cell while acting on another. Cytokine pathways are relatively complex, and more in-depth knowledge of these pathways, as well as their interactions with other molecules, is being published. These mediators play a pivotal role in the metabolism of the synovial membrane and articular cartilage in health and disease.

Most notable of the catabolic cytokines are IL-1 and TNF-α, which can be secreted from chondrocytes and synoviocytes. Both have been demonstrated to be upregulated beyond a normal level in osteoarthritis, promoting production of MMP, nitric oxide, and prostaglandin E2 (PGE2), as well as inhibiting aggrecan and type II collagen synthesis. Although both IL-1 and TNF have relatively similar actions, it is thought that IL-1 is the most important of the pro-inflammatory cytokines. In vitro, the two molecules do appear to potentiate each other, and TNF has been shown to stimulate IL-1. In addition to having these effects, IL-1 has also been shown to inhibit the production of natural anti-inflammatory molecules such as the MMP inhibitors (tissue inhibitor of matrix metalloproteinase, or TIMP) and interleukin-1 receptor antagonist (IL-1Ra), which potentiates the catabolic cascade.

The modulatory or regulatory cytokines, such as IL-4, IL-10, and IL-13, have actions that balance or modulate the pro-inflammatory cytokines, namely IL-1 and TNF. They have been shown to inhibit the synthesis of IL-1 as well as to promote the synthesis of the natural inhibitors, specifically the TIMPs and IL-1Ra. IL-6 has a mixed mode of action that includes magnifying the effects of IL-1 while promoting synthesis of the TIMPs.

Cytokines that promote the anabolic cascade of cartilage metabolism, such as insulin-like growth factor (IGF) and transforming growth factor (TGF), play a role in osteoarthritis. These molecules have been shown to promote chondrocyte production of matrix molecules such as proteoglycans and type II collagen. Thus, anabolic cytokines can be helpful in reparative attempts in diseased joints. The use of anabolic cytokines in treatment protocols of osteoarthritis is an area of current research.

Although not classified as cytokines, nitric oxide (as well as other oxygen-derived free radicals) and prostaglandins are increased in joints with osteoarthritis. Free radicals play a role in the degradation of hyaluronan and collagen. Cells have been shown to produce nitric oxide in response to IL-1, and its production has been related to inhibition of chondrocyte anabolic activities. Association with activation of MMPs and the reduction in the natural inhibitors has also been observed with nitric oxide, although this molecule’s specific role in osteoarthritis is still somewhat controversial. Also associated with decrease in anabolic synthesis is the E series of prostaglandins. PGE2 has been shown to be increased in the synovial fluid of horses with osteoarthritis and has been correlated with both synovitis and clinical lameness as well as being produced after stimulation with IL-1 and TNF in vitro.

**Natural Inhibitors of MMPs and Cytokines**

The biologic response to IL-1 and TNF occurs after the molecules bind to a specific receptor. Both molecules have at least one mechanism by which their activity is blocked by a natural inhibitor. One example of a natural inhibitor of IL-1 is IL-1Ra, which has affinity for the IL-1 receptor, but when it binds to the receptor, it does not elicit a biologic response, and thus it acts as a natural inhibitor of IL-1. In the case of TNF, the membrane-bound receptors can be secreted or solubilized (in this form, there is no way to signal a biologic response once bound to TNF). They maintain the affinity for the TNF molecule and, in thus binding the molecule, prevent it from binding a membrane-bound receptor. Numerous in vitro and in vivo studies have been carried out using natural inhibitors of the cytokines with very promising results (see Chapter 84).

Like the cytokines, natural inhibitors of the MMPs also exist, termed TIMPs. Four different TIMPs have been described, three of which (TIMP-1, TIMP-2, and TIMP-3) are thought to be active in inhibition of joint-related functions. Synthesized by numerous cells that include chondrocytes and synoviocytes, these inhibitors bind one-to-one with MMPs to form an inactive complex. Believed to play an important role in the normal regulatory mechanism of the joint environment, these inhibitors have been shown to be present in abnormal levels in human osteoarthritic cartilage. Therapeutic intervention using TIMPs has not appeared to advance as rapidly as cytokine inhibitor therapy, which may suggest a less global role in osteoarthritis, although more research is needed.

In summary, a vast number of mediators are involved in joint metabolism in both health and disease. This chapter has only outlined the major molecules and the current level of understanding. Given the discovery of new mediators and common pathways, substantial changes in our
understanding of osteoarthritis should be expected in the next decade. Additional information on this subject can be found in Chapter 79.

Clinical Manifestations of Osteoarthritis

Sources of Pain

Joint-related problems account for the greatest single economic loss to the horse industry, much of which can be related to osteoarthritic pain. Although the articular cartilage is devoid of innervation, the surrounding tissues are rich in unmyelinated C fibers. The capsule, synovium, tendons, ligaments, periosteum, and bone have all been defined as sources of pain in osteoarthritic cases. Sensory nerves are known to respond both to mechanical stimuli, such as stretching, and to chemical mediators. Mediators such as kinins and the neuropeptides (e.g., substance P) have been shown to stimulate pain fibers directly. These mediators, along with others, such as PGE2 and IL-1, sensitize fibers to be more reactive after mechanical stimulation. Upregulation of pain receptors and involvement of the central nervous system (i.e., the spinal nerves) has also been demonstrated in osteoarthritis.64 Elevated levels of substance P have been observed in both equine and human patients with osteoarthritis, and they can stimulate monocytes to release other pro-inflammatory cytokines such as IL-1 and TNF.65-67

In both horses and humans, correlation between clinical signs and disease severity is poor. In humans, there is an increased chance of reporting pain with increasing radiographic changes consistent with osteoarthritis, but a significant number of people report pain despite normal radiographs, and many individuals with unequivocal knee osteoarthritis deny having pain. Similar parallels can be drawn from equine patients, although anatomic location in both horses and humans appears to play a part in the correlation between clinical pain and the objective parameters. One explanation for the lack of association between pain and structural damage is the lack of sensitivity of outcome parameters, such as radiographs. Many of the soft tissue structures responsible for the pain, such as joint capsule, ligaments, and menisci, are poorly imaged using radiographs. In fact, the importance of soft tissue in joint health is underscored by the fact that quadriceps weakness is a risk factor for human knee osteoarthritis. Multiple studies have shown that strengthening exercises are an effective method of reducing pain and improving function in people with osteoarthritis.66-70

It is also believed that the periosteum and bone can play a significant role in osteoarthritic pain. People report focal pain in the area of osteophyte growth, and it is believed that growth of the osteophyte may result in elevation and stretching of the richly innervated periosteum.64 In some cases, the subchondral bone plate appears to be a source of pain, although not all horses with subchondral cystic lesions demonstrate clinical lameness.71 Increases in intravascular pressure have been demonstrated in osteoarthritis, and there is evidence to link this with pain in people, especially following reduction of symptoms after cortical fenestration.64 Similar mechanisms have been proposed for horses, and decompression of cystic lesions has led to improved lameness scores.

Clinical Parameters

An increase in synovial fluid or synovial pressure is a common finding, especially in joints with excessive joint distention. Thought to be initiated by inflammatory events occurring in the joint, synovial effusion is in part a result of increased vascular permeability (ingress) and a decrease in lymphatic drainage (egress). This net increase in fluid results in an abnormal usage of the joint for both mechanical and pain-related reasons. If not controlled, the inflammatory process may lead to changes in the synovium and the joint capsule, which are often observed as a decreased range of motion. Although an increase in synovial fluid can be solely responsible for decreases in range of motion, edema and a decreased pain threshold most likely also contribute. More chronic changes, such as fibrosis in the synovial membrane and joint capsule, can also be observed histologically.

Changes in the content of the synovial fluid are also observed in most cases of osteoarthritis, and reduction in viscosity is one of the oldest measures of a diseased joint. A rough evaluation of viscosity is often made by handling a tenacious string of synovial fluid between the evaluator’s fingers. The loss in viscosity is typically attributed to a decrease in hyaluronan concentration as well as to depolymerization or shortening of the molecule.72 The large variation in scientific methods and the time-consuming nature of measuring synovial fluid viscosity often make this measurement clinically impractical. The addition of acetic acid leading to precipitation of mucin or a “mucin clot” is a quick and easier but less specific or sensitive way to measure synovial fluid quality. This, in combination with gross observation of the synovial fluid, which is usually pale yellow to clear and free of flocculent material, has been used in the field to assess quality. In a laboratory setting, the determination of synovial fluid total protein is often useful in relation to the degree of synovitis and also has been correlated to articular cartilage damage arthroscopically.73 Cytologic examination of the synovial fluid also is routinely performed in the laboratory. Although synovial fluid total protein and cytology is not diagnostically very specific or sensitive, it can be useful in some cases, especially those with extreme values (Table 83-2).

Recently, more sophisticated methods of measuring cartilage-specific (aggrecan and type II collagen) synthetic and degradation molecules have become available for use on synovial fluid and serum of horses with osteoarthritis. These biomarkers show promise in early detection and staging of equine joint disease, although more clinical research is needed.33,73

As previously mentioned, the usefulness of radiographs is somewhat limited in osteoarthritis, but, because of their ease, they have historically been a method for evaluating joint disease. Although often not correlated to the severity of clinical signs, periarticular osteophytes, joint-space narrowing, subchondral bone sclerosis or lysis, and the presence of osteochondral fragments are typical features that can be present radiographically in an osteoarthritic joint (Table 83-3).

Other imaging modalities such as ultrasonography and magnetic resonance imaging (MRI) have more recently gained acceptance in veterinary medicine. The ability of ultrasonography to image soft tissues, including articular cartilage, makes it an especially useful adjunctive diagnostic

*Significant elevations in leukocyte counts and total protein concentration occur within the first 12 hours in experimentally inoculated joints. Values shown represent those observed at 24 hours.

Leukocyte counts and total protein concentrations correspond to the maximum values that typically occur within the first 24 hours.

Synovial response to lidocaine and mepivacaine are comparable.
Advanced articular response to advanced tissue does not necessarily return to its original structure and tissue structures replace the damaged tissue, but that the hand, has a more limited meaning and suggests that cells define healing as the restoration of structural and functional integrity, whereas regeneration suggests the tissue will heal. 

Osteochondral disintegration of joint surfaces or articular cartilage degeneration and loss. Typically described by the dimensions of the lesion and its depth into the tissue; both of these factors, as well as anatomic location and weightbearing, play a significant role in the degree of healing and return to normal function. 

It is important to note discrepancies in the cartilage repair literature regarding the definition of full-thickness defects. This term has been used by some to describe lesions including only the noncalcified cartilage (superficial, intermediate, and deep, but not the calcified cartilage layers) all the way to lesions that extend past the subchondral bone plate. Until recently, the true depth was known only if histologic confirmation was performed. However, after studies using arthroscopic visualization of experimental cartilage defects were correlated directly to histologic sections, some degree of confidence about the depth of defects can be made. Today, most authors use full-thickness articular cartilage defects to describe a lesion through the calcified cartilage layer but not involving the subchondral bone plate.

It is believed that full-thickness defects greater than 3 to 5 mm² in surface area have a poor capacity for repair. In general, defects of this size range are difficult to identify grossly 1 year after they are created, whereas larger defects show good initial healing but degenerate within a year’s time. Partial-thickness defects are believed to have some minor capacity for healing, but typically they appear neither to be progressive nor to compromise joint function, and they are, therefore, not the focus of most cartilage repair procedures. Clinically, partial-thickness lesions are debrided of any surface fibrillation without debriding deeper. This is because currently used cartilage-repair processes do not provide a repair tissue that is clearly better than the tissue in a partial-thickness defect. 

Historically, two different repair mechanisms are described for articular cartilage: intrinsic and extrinsic. Intrinsic, as the name implies, occurs from within the cartilage. Thus, intrinsic repair relies on the limited capacity of the chondrocytes to divide and repair the damage. A type of intrinsic repair termed matrix flow describes healing lesions that have chondrocytes and surrounding matrix that appear to flow from the peripheral cartilage edges into the defect in an attempt to fill the lesion. Small defects appear to repair via this process. Extrinsic repair derives cells and other factors contributing to the repair process from sources other than the chondrocytes. One example is repair following surgical perforation of the subchondral bone plate, which is believed to allow stem or progenitor cells as well as growth factors access to the defect, thus enhancing the repair of large defects, which would otherwise exhibit poor healing. The currently accepted method of subchondral perforation is called subchondral bone microfracture. Contrary to historic beliefs, mounting evidence suggests that progenitor cells may exist in the surface layer of articular cartilage, thereby challenging the distinction of intrinsic and extrinsic healing, although it is still accepted that large lesions most likely derive most of their reparative capacity from extrinsic sources. Another example of extrinsic repair is through the implantation of chondrocytes obtained from an external source, which are typically suspended in some form of scaffold and secured into the defect. Greater detail on specific cartilage repair procedures can be found in Chapter 84.

*Specific pathophysiologic mechanisms and reasons for disproportionate representation of changes among and between joints remain unclear. 
†Seldom used as a marker of disease progression because of problems with technical aspects of radiographic positioning and focal-film distance.

A tool in osteoarthritis. The level of sophistication and general knowledge in equine ultrasonographic joint anatomy has greatly increased in the last decade, making joint ultrasonography a standard tool. Likewise, with increased knowledge of normal anatomy and increased availability of equine-dedicated MRI units, this modality will surely gain greater acceptance. The use of MRI in the human orthopedic field is commonplace, largely because of the ability to image all of the joint tissues in a three-dimensional space.

### Cartilage Repair

An observation made in 1743 that “cartilage once destroyed never heals” is still accurate today. Modern nomenclature defines healing as the restoration of structural and functional integrity, whereas regeneration suggests the tissue will be identical to that of the original. Repair, on the other hand, has a more limited meaning and suggests that cells and tissue structures replace the damaged tissue, but that the tissue does not necessarily return to its original structure or function. The degree of damage to normal articular cartilage is typically described by the dimensions of the lesion and its depth into the tissue; both of these factors, as well as anatomic location and weightbearing, play a significant role in the degree of healing and return to normal function.

It is important to note discrepancies in the cartilage repair literature regarding the definition of full-thickness defects. This term has been used by some to describe lesions including only the noncalcified cartilage (superficial, intermediate, and deep, but not the calcified cartilage layers) all the way to lesions that extend past the subchondral bone plate. Until recently, the true depth was known only if histologic confirmation was performed. However, after studies using arthroscopic visualization of experimental cartilage defects were correlated directly to histologic sections, some degree of confidence about the depth of defects can be made. Today, most authors use full-thickness articular cartilage defects to describe a lesion through the calcified cartilage layer but not involving the subchondral bone plate.

It is believed that full-thickness defects greater than 3 to 5 mm² in surface area have a poor capacity for repair. In general, defects of this size range are difficult to identify grossly 1 year after they are created, whereas larger defects show good initial healing but degenerate within a year’s time. Partial-thickness defects are believed to have some minor capacity for healing, but typically they appear neither to be progressive nor to compromise joint function, and they are, therefore, not the focus of most cartilage repair procedures. Clinically, partial-thickness lesions are debrided of any surface fibrillation without debriding deeper. This is because currently used cartilage-repair processes do not provide a repair tissue that is clearly better than the tissue in a partial-thickness defect. 

Historically, two different repair mechanisms are described for articular cartilage: intrinsic and extrinsic. Intrinsic, as the name implies, occurs from within the cartilage. Thus, intrinsic repair relies on the limited capacity of the chondrocytes to divide and repair the damage. A type of intrinsic repair termed matrix flow describes healing lesions that have chondrocytes and surrounding matrix that appear to flow from the peripheral cartilage edges into the defect in an attempt to fill the lesion. Small defects appear to repair via this process. Extrinsic repair derives cells and other factors contributing to the repair process from sources other than the chondrocytes. One example is repair following surgical perforation of the subchondral bone plate, which is believed to allow stem or progenitor cells as well as growth factors access to the defect, thus enhancing the repair of large defects, which would otherwise exhibit poor healing. The currently accepted method of subchondral perforation is called subchondral bone microfracture. Contrary to historic beliefs, mounting evidence suggests that progenitor cells may exist in the surface layer of articular cartilage, thereby challenging the distinction of intrinsic and extrinsic healing, although it is still accepted that large lesions most likely derive most of their reparative capacity from extrinsic sources. Another example of extrinsic repair is through the implantation of chondrocytes obtained from an external source, which are typically suspended in some form of scaffold and secured into the defect. Greater detail on specific cartilage repair procedures can be found in Chapter 84.
Repair of clinically significant lesions (i.e., greater than 5 mm in diameter), which requires extrinsic repair methods, appears to be hampered by a less-than-optimal aggrecan, type II collagen content, and re-formation of normal subchondral bone and calcified cartilage layers. As was previously described, all of these components are integral to the normal function of articular cartilage and hence the joint. Significant improvements in re-establishment of the type II collagen content and to some degree aggrecan have been made recently, but little has been done to improve, enhance, or even control the re-formation of the subchondral bone plate or calcified cartilage layer. Experimental defects have been shown to heal through an influx of granulation tissue, which is characterized by types I and III collagen, and by little proteoglycan or aggrecan in the first 6 weeks. The granulation tissue is then slowly replaced with increasing amounts of type II collagen and aggrecan by chondrocyte-like cells. At best, a hyaline-like tissue is formed, and the biomechanical and biochemical properties of this tissue leave much to be desired. Although modern science has made great leaps in improving the in vitro character of tissue-engineered cartilage, the absence of normal physiologic mechanical stimuli appears to be a rate-limiting step in vivo, given the critical role it plays in tissue integration and long-term survival of these creations. Interestingly, it has been observed in humans that the quality of the repair tissue is not always directly correlated to the functional outcome of the patient. Thus, less emphasis is now being placed on the regeneration of the articular cartilage and more on long-term improvement in function. In some older human patients, 5 years of dramatic pain relief, thus delaying joint term improvement in function. In some older human regeneration of the articular cartilage and more on long-

CHAPTER 84

Principles of Treatment of Joint Disease
David D. Frisbie

Over the last decade, significant advancements have been made in the understanding of medical and surgical treatment of equine joint disease. Many of these advances originally were aimed at helping humans, but the principles have been adapted for use in the horse. Advances in understanding pathophysiology, novel surgical techniques, improved surgical equipment, and more-sophisticated imaging modalities have led to improved treatment of joint disease.

It is important to focus on the two main treatments for joint disease: the relief of pain to regain functional use of the diseased joint and the arrest of disease progression. In many cases, generalized osteoarthritis (OA) is treated using medical management and exercise protocols, whereas full-thickness articular cartilage damage usually involves some surgical intervention.

SURGICAL TREATMENT
Diagnostic and Surgical Arthroscopy

Equine arthroscopy was first described as a diagnostic tool to visualize lesions that were undetectable using x-ray or other routine imaging procedures, but it was soon employed for therapeutic purposes, such as surgical removal of osteochondral fragments. Arthroscopy is now considered part of routine equine surgery and has, for the most part, replaced arthrotomy. It allows better visualization of the joint anatomy and inflicts less damage to the joint capsule and surrounding tissues, leading to quicker return to use and a more favorable outcome for the horse. Since the 1980s, various publications have described arthroscopy in the horse; many of the early publications only described various techniques and approaches to joints, with more-specific outcomes and prognosis for specific pathologies following in subsequent publications. Most of the published work has been compiled in equine-specific texts. The equipment used for arthroscopy and the surgical technique is discussed in Chapter 14.

Arthroscopy has a diagnostic and a therapeutic function in joint disease. Even with modern imaging modalities, it is still considered the gold standard for diagnosing equine joint problems. The cost and availability of arthroscopic equipment, along with arthroscopy’s specificity and sensitivity when compared to more complex imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) and the expertise needed to perform definitive joint ultrasound, will likely keep arthroscopy in the forefront of diagnostics for equine joint disease for many years. This is especially true in cases that show no demonstrable or questionable joint lesions using traditional imaging modalities, even though the horse has localized clinical pain based on diagnostic analgesia.

In recent years, more joint pathology, such as meniscal and cruciate lesions, has been described. This may be because diagnostic arthroscopy, especially in the stifles joint, has become more accepted. Therefore, these types of lesions, which are not detectable using radiography, are being recognized more often. With an increased awareness of how often these types of lesions occur, further work is being focused on therapeutic treatments. This is especially true in the field of cartilage resurfacing and meniscal pathology, with many of the therapeutic avenues pursued in equine practice representing the current state of the art in human medicine.

Another advantage of the use of arthroscopy is the potential benefit of lavage. Arthroscopy is often performed using fluid to distend the joint for better visualization. The accompanying egress of joint fluid, which potentially contains cytokines and cartilage wear particles, may be therapeutically beneficial, even when lavage is performed as a sole treatment in cases of osteoarthritis. However, the benefit of lavage is controversial, and it does not work in cases with significant definable disease such as meniscal tears. Research also has shown that when lavage is performed with large-gauge needles (14 gauge), it is not as effective as using arthroscopic cannulas. Distention of the joint can be accomplished using inert gas, which can be especially helpful if bleeding of intrasynovial tissues impairs visualization when a fluid medium is being used.

In general, arthroscopy is of more therapeutic benefit in acute than in chronic cases. For example, removing a fresh osteochondral fragment before osteoarthritis can develop typically produces a better outcome after surgery than removing a chronic osteochondral fragment after osteoarthritis has developed. However, there are some exceptions, such as osteonecrosis and cartilage fibrillation of the third carpal bone, which can be successfully managed using arthroscopy.

Principles of Treatment of Joint Disease
David D. Frisbie

Over the last decade, significant advancements have been made in the understanding of medical and surgical treatment of equine joint disease. Many of these advances originally were aimed at helping humans, but the principles have been adapted for use in the horse. Advances in understanding pathophysiology, novel surgical techniques, improved surgical equipment, and more-sophisticated imaging modalities have led to improved treatment of joint disease.

It is important to focus on the two main treatments for joint disease: the relief of pain to regain functional use of the diseased joint and the arrest of disease progression. In many cases, generalized osteoarthritis (OA) is treated using medical management and exercise protocols, whereas full-thickness articular cartilage damage usually involves some surgical intervention.

SURGICAL TREATMENT

Diagnostic and Surgical Arthroscopy

Equine arthroscopy was first described as a diagnostic tool to visualize lesions that were undetectable using x-ray or other routine imaging procedures, but it was soon employed for therapeutic purposes, such as surgical removal of osteochondral fragments. Arthroscopy is now considered part of routine equine surgery and has, for the most part, replaced arthrotomy. It allows better visualization of the joint anatomy and inflicts less damage to the joint capsule and surrounding tissues, leading to quicker return to use and a more favorable outcome for the horse.\(^1\) Since the 1980s, various publications have described arthroscopy in the horse; many of the early publications only described various techniques and approaches to joints, with more-specific outcomes and prognosis for specific pathologies following in subsequent publications. Most of the published work has been compiled in equine-specific texts.\(^1,2\) The equipment used for arthroscopy and the surgical technique is discussed in Chapter 14.

Arthroscopy has a diagnostic and a therapeutic function in joint disease. Even with modern imaging modalities, it is still considered the gold standard for diagnosing equine joint problems. The cost and availability of arthroscopic equipment, along with arthroscopy’s specificity and sensitivity when compared to more complex imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) and the expertise needed to perform definitive joint ultrasound, will likely keep arthroscopy in the forefront of diagnostics for equine joint disease for many years. This is especially true in cases that show no demonstrable or questionable joint lesions using traditional imaging modalities, even though the horse has localized clinical pain based on diagnostic analgesia.

In recent years more joint pathology, such as meniscal and cruciate lesions, has been described. This may be because diagnostic arthroscopy, especially in the stifle joint, has become more accepted. Therefore, these types of lesions, which are not detectable using radiography, are being recognized more often. With an increased awareness of how often these types of lesions occur, further work is being focused on therapeutic treatments. This is especially true in the field of cartilage resurfacing and meniscal pathology, with many of the therapeutic avenues pursued in equine practice representing the current state of the art in human medicine.

Another advantage of the use of arthroscopy is the potential benefit of lavage. Arthroscopy is often performed using fluid to distend the joint for better visualization. The accompanying egress of joint fluid, which potentially contains cytokines and cartilage wear particles, may be therapeutically beneficial, even when lavage is performed as a sole treatment in cases of osteoarthritis. However, the benefit of lavage is controversial, and it does not work in cases with significant definable disease such as meniscal tears. Research also has shown that when lavage is performed with large-gauge needles (14 gauge), it is not as effective as using arthroscopic cannulas.\(^3,4\) Distention of the joint can be accomplished using inert gas, which can be especially helpful if bleeding of intrasynovial tissues impairs visualization when a fluid medium is being used.

In general, arthroscopy is of more therapeutic benefit in acute than in chronic cases. For example, removing a fresh osteochondral fragment before osteoarthritis can develop typically produces a better outcome after surgery than removing a chronic osteochondral fragment after osteoarthritis has developed. However, there are some exceptions, such as osteonecrosis and cartilage fibrillation of the third carpal bone, which can be successfully managed using arthroscopy.

References

Another consideration regarding arthroscopic surgery is the documentation of the surgical procedure. Since the 1990s, reduction in cost and increases of availability of video and still-capture devices have allowed real-time documentation of arthroscopic surgery to be made and kept as part of the medical record. This real-time information is embraced by trainers and owners as a means of understanding the pathology and treatment procedures, as well as providing more specific information about the surgery. Detailed drawings of many intra-articular surfaces can also be helpful in documenting surgical findings (Fig. 84-1).

Removal of Osteochondral Fragments

In most instances, osteochondral fragments are removed when they are diagnosed in conjunction with clinical lameness. Some fragments are considered relatively benign, and removal is not indicated without clinical lameness. The routine use of arthroscopy has improved the outcome of osteochondral fragment removal as compared to removal using arthrotomy. Outcomes related to osteochondral fragment removal are presented in Table 84-1, and specific arthroscopic approaches to anatomic joints can be found detailed in this text and in published references.

In general, diagnostic visualization of the entire joint cavity is performed prior to fragment removal. When multiple fragments are present, typically the smaller fragments are removed first. This postpones the need to increase the size of the instrument portal and delays the potential for subsequent reduced visualization until the end of the surgery. Very large fragments can be broken into smaller pieces using a rongeur or osteotome to avoid excessive portal size. Hand curets are typically used to débride the parent bone down to the appropriate level as well as to smooth any edges to prevent trauma to opposing joint surfaces postoperatively. Prior to finishing arthroscopic surgery, typically the joints are lavaged with fluids while a final inspection of the joint is completed to ensure all debris has been removed. Debris often accumulates in certain locations within a specific joint, and knowledge of these locations often aids in finding debris that has inadvertently escaped removal by lavage alone.

Reconstruction of Intra-articular Fractures

Once damaged, bone can be repaired so that it is indistinguishable from the original tissue. However, articular cartilage does not have the same ability to heal. Therefore, correct anatomic alignment and reconstruction of the fracture gap, especially the articular component, is integral to the repair process and determines the long-term resolution of intra-articular fractures.

Arthroscopic visualization during the reconstruction of the articular component of the fracture is recommended to ensure the best possible outcome in a high-motion joint. In many cases, loose debris is débrided and flushed from around and in the fracture gap, allowing more anatomically correct reduction and better stabilization of the fracture. In some cases, such as with slab fractures of the third carpals bone, assessment of the articular component dictates the surgical procedure, namely repair or removal of the fracture fragment. Common intra-articular fractures encountered in equine athletes are condylar fractures of the third metacarpal (MCIII) and third metatarsal (MTIII), third carpal bone slab fractures, and sagittal fractures involving the proximal phalanx. Most cases of intra-articular fractures are repaired using internal fixation and lag-screw principles. These are covered in other chapters of the text, but some treatments and outcomes are listed in Table 84-2.

Synovectomy

Equine synovium is occasionally removed locally (partial synovectomy) to help arthroscopic visualization, but synovectomy can also be performed as a therapeutic treatment, most often in cases of septic arthritis. With sepsis, the synovial membrane can be laden with fibrin. Fibrin is thought to harbor bacteria; thus removal of the involved synovium is thought to aid in treatment and potentially prevent recurrence of the septic process. Some septic equine joints appear to produce more fibrin than others (tarsocrural, distal phalangeal, and elbow joints are among the most prolific), which requires visualization of the joint space and synovectomy rather than ingress-egress flushing using large-gauge needles. In some cases of chronic osteoarthritis, marked hypertrophy of the synovium can be encountered, and current practice is to perform a subtotal or complete synovectomy of the affected membrane to reduce cytokine production as well as physical impingement. The carpal joints and the metacarpophalangeal and metatarsalophalangeal joints appear to benefit clinically from this type of treatment.

The role that the synovial membrane plays in equine joint disease is not as well characterized as it is in humans. In human osteoarthritis, the synovial membrane is thought to play a secondary role to the cartilage lesion in the pathogenesis. Conversely, in rheumatoid arthritis, the synovial membrane is thought to be the primary instigator and to propagate the ongoing degeneration of the cartilage. Thus, an effective method of controlling rheumatoid arthritis in people is through synovectomy, although it has a limited duration of clinical effectiveness. A rheumatoid condition has not been identified in the horse.

Different methodologies have been used to accomplish synovectomy, including use of surgery, chemicals, and radioisotopes. Typically, surgical methods in horses use motorized synovial resection. Experimentally, synovectomy has been performed in normal horses and has shown no ill effects, but the regeneration of the synovial membrane was slower than expected when compared to other species.

Joint Resurfacing

Partial-thickness lesions and full-thickness articular cartilage lesions greater than 5 mm in diameter do not heal spontaneously in the horse. In spite of the recent interest in assessing treatments for chondral defects, efforts have been under way for more than 250 years to heal articular cartilage with only moderate progress. The reason is related to the highly specialized nature of articular cartilage and the need for an intact structure to perform its biochemical and physiologic functions. Damage to articular cartilage is common in horses and typically is described in two forms, chronic degenerative

*The prognoses have been graded as excellent (80% to 90% chance of athletic soundness), good (60% to 80%), guarded (40% to 60%), and poor (<40%) and usually refer to the ability to race after injury. These are approximate percentages extrapolated from the literature because these categories are not always used by each author and a definition of these categories is not usually given. "Favorable" has been graded with "good." In general, the prognosis given is for horses with no radiographic signs of osteoarthritis (i.e., the horse is given its best chance of recovery).

<sup>a</sup>These fractures do not cause major joint instability.

<sup>1</sup>Hazard ratio was used to compare the racing performance of the treated with that of a control group, taken from the horse registry for the same period. A hazard ratio of approximately 1 means that the same number of treated horses dropped out of racing as the controls. A hazard ratio of 2 means that twice as many treated horses were lost as the controls.

<sup>§</sup>Guarded to good used when the percentages spanned 2 ranges.

lesions and acute damage. Chronic lesions are often considered osteoarthritis, and whereas these lesions would benefit from joint resurfacing, this type of lesion is the most challenging in which to achieve long-term repair because of generalized joint pathology that is not addressed with most current joint-resurfacing techniques. Conversely, acute lesions typically comprise a discrete or focal area of cartilage loss without other chronic manifestations of joint degeneration. Such lesions are currently best treated with equine joint-resurfacing techniques.

The outcome of cartilage repair is typically assessed on biochemical content (including type II collagen and aggrecan), histologic appearance (resemblance to hyaline cartilage), biomechanical properties, and functional outcome of the joint and patient. As a general rule, it appears that cartilage in younger patients has a better capacity for repair compared to that of older patients.

When intra-articular osteochondral fragmentation occurs in the horse, surgical treatment involves removal of the fragment and débridement of the damaged cartilage and subchondral bone. In general, because of a generalized poor regenerative response, articular cartilage is usually minimally débrided, doing no more than is necessary to remove damaged cartilage. Partial-thickness cartilage lesions are typically not converted into full-thickness lesions, but rather the fibrillated cartilage is removed, leaving the intact cartilage below the fibrillated cartilage in place. In the case of a full-thickness lesion, the edges of the damaged articular cartilage are débrided until cartilage that is firmly attached to the subchondral bone plate is reached. The edges of the

*The prognoses have been graded as excellent (80% to 90% chance of athletic soundness), good (60% to 80%), guarded (40% to 60%), and poor (<40%) and usually refer to the ability to race after injury. These are approximate percentages extrapolated from the literature because these categories are not always used by each author and a definition of these categories is not usually given. Favorable has been graded with good. In general, the prognosis given is for horses with no radiographic signs of osteoarthritis (i.e., the horse is given its best chance of recovery).

1 Articular fractures of long bones (except for the metacarpus and metatarsus) have not been included because of insufficient numbers from which to derive prognoses or other complicating factors, or both.

2 All fractures repaired surgically with stab incisions or arthrotomies, or both, except C3 slabs, in which repair was guided by arthroscopic visualization. Two grades given when percentages spanned two categories.

C3, third carpal bone; M, medical; MC, metacarpus; P, phalanx; S, surgical; SB, Standardbred; TB, Thoroughbred.

cartilage are débrided so that they have a sharp vertical border. The bone is always débrided down to a level of the subchondral bone plate so as to fully remove the calcified cartilage, which has been shown to impede the repair process. When necrotic bone is encountered, it is débrided aggressively to ensure that healthy bleeding bone is being left in the lesion.

The previous chapter covered general concepts regarding treatment based on the lesion depth, size, and basic repair or treatment options. Two basic approaches are historically thought of in joint resurfacing: stimulated endogenous repair and transplantation or grafting of tissues. Although these techniques are covered as separate entities, many cutting-edge approaches are combining the techniques as well as augmenting either or both techniques with growth factor supplementation.

**Stimulated Endogenous Repair**

Because bone marrow has a good supply of both stem cells and growth factors thought to be integral to cartilage health and repair, direct communication of articular lesions to these elements beneath the subchondral bone plate has been a cornerstone of stimulated cartilage repair. Growth factors believed to be important in cartilage repair include insulin-like growth factor-1 (IGF-1), transforming growth factor-β (TGF-β), and bone morphogenetic proteins (BMP) 2 and 7. Access to these marrow elements has been facilitated by various surgical techniques including abrasion arthroplasty, which involves débridement to the level of the subchondral plate; spongialization, which is débridement past the subchondral plate into cancellous bone; focal drilling to the depth of cancellous bone in discrete locations throughout the cartilage lesion (osteostixis); and subchondral bone microfracture, which also penetrates to the level of the subchondral bone plate in discrete locations. Current literature and clinical practice do not favor spongialization, in part because it is thought to destabilize the subchondral bone plate.

Based on the human and equine literature, the current recommendations for stimulated endogenous repair of an articular lesion are débridement of lesions to the level of the subchondral bone plate (abrasion arthroplasty) alone or in conjunction with subchondral bone microfracture. If the lesion crosses the subchondral bone plate into the cancellous bone, the addition of subchondral bone microfracture is probably not necessary. In the presence of sclerotic bone, the lesion is débrided to a depth that produces petechial bleeding (in the absence of fluid pressure) but does not enter the cancellous bone. In this case, subchondral bone microfracture is also used.

Currently, subchondral bone plate drilling is not widely used based on subsequent formation of subchondral bone cysts and poor histologic appearance of repair tissue, especially when compared to other, more recently developed techniques such as subchondral bone microfracture. The greater depth of penetration, smooth penetration through the bone, and heat generated with the drilling process probably contribute to the less-than-optimal repair tissue. Bone cyst formation associated with the drilling technique is probably a result of synovial fluid movement into the bone through the drill holes (see Chapter 92).

Subchondral bone microfracture allows access to the cells and growth factors beneath the subchondral plate, without destabilization of the subchondral plate’s biomechanical stability. In addition, the penetration of the stainless steel bone awl causes cracks in the bone as well as spicules of bone that protrude from the penetration site, both of which are believed to aid in the attachment of the repair tissue. Experimental studies have demonstrated that large articular cartilage defects (1 to 2 cm in diameter) débrided to the level of the subchondral bone have significantly greater volume of healing tissue following subchondral bone microfracture compared to defects that were débrided to the level of the subchondral bone plate but did not undergo microfracture. Biochemical analysis of the repair tissues also has shown a greater type II collagen content in repair tissue of microfractured defects in two experimental studies, although histologic appearance of the repair tissues was similar.

Further improvement in the repair tissue obtained following subchondral bone microfracture has been achieved by supplementing IGF-1 and interleukin-1 (IL-1) receptor antagonist using gene transfer. Experimental work assessing subchondral bone microfracture has also confirmed the poor attachment of repair tissue in areas where the calcified cartilage layer had been incompletely removed. Confirmation of the level of débridement can be achieved using a microarthroscope or focusing close to the defect margins with a standard arthroscope. A granular appearance of the defect should be evident, differentiating the subchondral bone plate from the glasslike appearance of the calcified cartilage layer. Following débridement of the lesion, microfracture holes are spaced 2 to 3 mm apart, avoiding communication between sites and penetrating approximately 2 mm into the bone (Fig. 84-2).

To date, no long-term follow-up on clinical results after resurfacing therapy have been published relating specifically to horses, although anecdotal reports have been promising. However, recent human data compared long-term follow-up to horses, although anecdotal reports have been promising. However, recent human data compared long-term follow-up...
of the most commonly used cartilage resurfacing techniques, autologous cartilage implantation (ACI) as described by Brittberg and subchondral bone microfracture first described by Steadman. The short-term and long-term results of this study show minor significant improvement with subchondral bone microfracture, with no significant differences in histologic appearance of repair tissue or patient outcome between the two techniques. Both of these techniques are considered better than debridement alone for most human and equine patients. Because subchondral bone microfracture does not require a second surgery and is less technically challenging compared to ACI, it is favored by most equine surgeons.

**Articular Grafting**

Many different tissues have been transplanted or grafted into cartilage defects; they include periosteal and perichondrial autografts, osteochondral, chondral, or isolated chondrocyte allografts or allografts, and stem cell transplants from bone marrow or fat. Periosteal and perichondrial grafts have been performed in laboratory animals with some success, but results in the horse have been very disappointing and are no longer a focus of ongoing research.

Osteochondral grafting procedures have been well developed for use in people, but they have had limited success in the horse. Early work in the horse demonstrated short-term success but resulted in long-term failures. Many of the failures with osteochondral grafting have been attributed to lack of congruency of the recipient and donor tissues as well as difficulties with surgical technique. Some concern also revolves around morbidity in the donor graft site. Typically, in people, a nonweightbearing region is used for donor harvest, reducing morbidity, but lack of suitable nonweightbearing donor tissue has been a limitation in horses. More recently, with the advent of specialized surgical tools designed for human osteochondral grafting, studies are under way using this technique in the horse. Surgical technique and donor site selection are the main hurdles yet to be overcome before this technique will reach mainstream practice.

Chondrocyte transplantation has been a very active area of equine research since the 1990s. Techniques using both allografts and autografts have been reported, but most work, especially in humans, has focused on autografts. The technique described by Brittberg and marketed by Genzyme is the most well studied grafting technique. This technique uses autologous chondrocytes harvested from a nonweightbearing region, usually the trochlea of the distal femur, followed by a four-week in vitro expansion of chondrocytes. The expanded cell population is then implanted during a second surgical procedure and held in the defect beneath autologous periosteum, which is sutured to the cartilage bordering the defect to create a watertight seal. Although this technique has been performed in horses with outcomes similar to those seen in people, the cost, laboratory facilities, need for multiple surgeries, and technical challenges of the procedure have limited its usefulness in clinical cases.

Techniques using frozen chondrocytes harvested from neonatal foals, which are implanted in a fibrin glue to help retain the cells in the chondral defect, have had some success in a limited number of chondral defects. The technique is being used more commonly in cystic defects to date. Other materials used to fill cystic lesions are discussed in Chapter 92.

Techniques using autologous chondrocytes harvested from the nonweightbearing region of the lateral trochlea of the distal femur, implanted into 15-mm diameter defects, have been successful in experimental equine trials. One of the tested procedures uses fibrin glue holding minced cartilage to a bioresorbable scaffold, which is subsequently stapled to the subchondral bone of the defect in a one-step surgical procedure. In comparable equine experimental trials this technique has been superior to the ACI technique. This technique is now undergoing human clinical trials, and because of the ease, cost, and promising results in equine experimental trials, it is likely to be used in equine clinical cases in the near future.

Considerable research is being directed toward the use of mesenchymal stem cells for implantation in cartilage defects. This cell population has been shown to improve healing in experimental animals, but gaining access to a sufficient number of stem cells without in vitro expansion is a hurdle yet to be resolved in horses.

**Arthrodesis**

Assisted fusion of a joint is sometimes indicated when destruction to the joint is beyond any other treatment. Although most commonly achieved through surgical methods typically involving internal fixation, arthrodesis can be carried out using chemical or laser-based methods as well.

In high-motion joints, such as the radiocarpal, midcarpal, metacarpophalangeal, and distal phalangeal joints, surgical fusion using internal fixation is required (see Chapter 85). The expectation of this procedure is to alleviate the pain associated with movement of the joint and to salvage the animal for nonathletic function. Conversely, arthrodesis of low-motion joints often carries a reasonable prognosis for athletic soundness and can be accomplished using surgical, chemical, or laser-based techniques. This is especially true for the proximal interphalangeal, tarsometatarsal, and distal intertarsal joints. Some risks have been identified with chemical fusion of joints because unexpected anatomic communications with other synovial and nonsynovial structures can be encountered. Thus, contrast studies outlining the structure and extent of the communication should be performed prior to chemical fusion, and caution should be used not to create further injury by overdistending the joint capsule.

In the distal tarsal joints, some initial studies have been performed comparing surgical drilling to ablation of the joint space using a laser in both clinical and experimental cases. Early results indicate that some decrease in time to resolution of clinical lameness may be seen for the laser-based procedure, but actual bony union of the joint space appears to occur more quickly with drilling. Further research comparing these techniques is needed, but the morbidity associated with the early reports using the laser favors the continued use of surgical arthrodesis in the distal tarsal joint, using the modified drilling technique. Further discussion of the principles of arthrodesis can be found in more detail in Chapter 85.
Joint Replacement
When reparative surgical procedures have failed, and the patient is unresponsive to medical management, many end-stage cases of osteoarthritis in people are treated using joint replacements, especially in the knee and hip. Joint replacement procedures are typically postponed until the patient is old enough that the implant will not fail during the expected remaining lifetime. Implant wear is improving, but it is still in the 10- to 20-year range, depending on the location and type of implant. Even in humans, where a large number of joint replacements are carried out annually, relatively high morbidity is associated with such procedures, especially related to implant loosening. With respect to equine joint replacement, cost of implant design and manufacturing, difficulties with prolonged nonweightbearing, and surgical morbidity continue to keep equine joint replacement out of mainstream clinical practice.

Aftercare
The aftercare for surgical joint treatment is often as important as the central treatment itself. Treatment goals and pathophysiology of healing tissue should be kept in mind when the aftercare protocol is being designed. Each aftercare protocol varies depending on the procedure, but a common focus is to minimize the duration to full return to function without compromising the athletic soundness of the patient. Following surgery, the goals are to provide support to the weakened areas, often through bandaging, casts, and controlled exercise, which can range from strict stall rest to specific graded exercise programs.

It is also well accepted that decreasing postoperative inflammation is beneficial in the healing process, as is controlling postoperative pain. Given that maximal inflammation in a surgical wound typically occurs 3 to 5 days postoperatively, systemic nonsteroidal anti-inflammatory medication is administered for at least this time period. The postoperative use of corticosteroids, although providing potent anti-inflammatory activities, is often contraindicated in the first 4 weeks because of their role in decreased cell metabolism, which affects healing time, as well as the decreased ability of the immune system to combat infection.

Other medications believed to have chondro-enhancing or chondroprotective qualities, such as hyaluronan or polysulfated glycosaminoglycans (Adequan), have also been studied in an attempt to demonstrate enhanced postoperative healing. However, they have not shown significant benefit in most studies, with the exception of decreasing adhesions in tendon sheaths.85-87

MEDICAL TREATMENT
There are two main goals for medical treatment of OA in the horse: reducing pain (lameness) and minimizing progression of joint deterioration. When formulating a treatment plan, the optimization of these goals will be influenced by an accurate and specific diagnosis, the stage of disease, severity, available treatment modalities, and rehabilitation time. Clinicians realize that treating joint disease is an art and does not follow any specific recipe.

Nonsteroidal Anti-Inflammatory Drugs
The use of NSAIDs for inhibiting the arachidonic acid cascade has been a mainstay for the treatment of joint disease for many decades. NSAIDs are typically used in cases of acute injury and are often accompanied by other treatment modalities. The renal and gastrointestinal side effects associated with NSAID administration limit their long-term use for treatment of joint disease. NSAIDs inhibit the production of prostaglandins and thromboxanes, especially the prostaglandin E (PGE) series, which is thought to be intimately involved in pain, altered cartilage metabolism, and ongoing inflammation in damaged joints (Fig. 84-3).

Traditionally, inhibition of PGEs and the resulting symptomatic pain relief has been viewed as a beneficial goal in treating OA (Fig. 84-4). Although relatively recent research has offered some suggestion that this inhibition may have

Figure 84-3. Schematic representation of inhibition of the inflammatory cascade by nonsteroidal anti-inflammatory drugs (NSAIDs) and corticosteroids.
long-term unfavorable effects on cartilage metabolism and does warrant further investigation, the current level of knowledge of these unfavorable effects most likely will not alter the use of NSAIDs in clinical practice. Research has also suggested that NSAIDs may have a role in mediating joint pain at the level of the spinal cord as well as locally, although specific research in this area has not been performed in the horse to date. In the early 1990s, a major advancement in NSAIDs for treatment of OA occurred with the identification of isoenzymes for the cyclo-oxygenase (COX) pathway (COX-1 and COX-2), and this does have current equine implications.

COX-1 has been associated with the housekeeping functions of the cyclooxygenase pathway. It is known to be constitutively produced and important in the balance of normal physiologic function of the gastrointestinal and renal systems, although it has a lesser role in the inflammatory cascade. COX-2 has mainly been associated with inflammatory events, especially those driven by macrophages and synovial cells, and has only minor roles in normal physiology, thus its “bad” or inducible role (Fig. 84-5). These findings have led to a paradigm that the anti-inflammatory properties of NSAIDs are mediated through the inhibition of the COX-2 enzyme, whereas the untoward effects occur as a result of their action on COX-1.

The protective role of COX-1 for the gastroduodenal mucosa has been shown both experimentally in laboratory animals and in human clinical trials. Furthermore, studies have shown that the greatest degree of damage to the gastroduodenal mucosa is generally caused by NSAIDs that preferentially inhibit COX-1. In fact, the preferential COX-2 inhibitor rofecoxib (Vioxx) was shown in human patients to induce ulceration that was actually lower than that produced in a randomized placebo group.

As with most biologic systems, complete inhibition of COX-2 may not be optimal; some value, albeit minimal, has been shown from expression of COX-2 as well as some demonstrable negative effects of COX-1 expression. More specifically, some low level of COX-1 expression is inducible during stress or inflammatory periods. Likewise, some constitutive expression of COX-2 has been demonstrated by the brain, kidney, and pancreatic islet cells, and it has a function in bone resorption. Furthermore, COX-2 suppression has been shown to delay gastric ulcer healing in rats. Thus, as Oscar Wilde said, “The pure and simple truth is rarely pure and never simple.”

To summarize: COX-1 is mainly responsible for the protective prostaglandins, but COX-2 plays some accessory role that is more important than previously thought. However, these facts still might not outweigh the beneficial effects of selective COX-2 inhibition in joint disease.

Research in humans has indicated that topical NSAID application can be clinically beneficial and may reduce systemic side effects. The effect of topical application of diclofenac liposomal suspension has been evaluated in an equine clinical trial with promising results. This product is indicated for horses with a finite number of affected joints, especially if prolonged treatment is not necessary.
Of products currently on the market, phenylbutazone remains one of the most popular NSAIDs for musculoskeletal pain in horses. Its cost, ease of administration, and relatively few side effects during short-term administration make it a good therapeutic choice. Flunixin meglumine and ketoprofen both have uses in treatment of equine OA, especially with some reports of fewer side effects; however the cost-to-benefit ratio often limits their use. The use of the first-generation COX-2 inhibitor carprofen is indicated in horses experiencing side effects or when extended treatment periods are predicted or side effects have been encountered with traditional NSAIDs.

Continued use of NSAIDs for treating acute inflammation associated with joint disease is likely for the foreseeable future. Selective COX-2 inhibitors will most likely be used more clinically as more information specific to the horse becomes available and the cost of these agents decreases. The currently applied NSAIDs in the horse are summarized in Table 84-3.

### Corticosteroids

More equine-specific research has been published on intra-articular (IA) administration of corticosteroids than any other equine joint medication. Since the introduction of IA corticosteroid use in the mid 1950s, controversy has existed over the risk-to-benefit ratio of this class of medication. Much of this controversy has been fueled from unsubstantiated statements in both the scientific and lay press. Studies showing potentially detrimental effects of corticosteroids on articular cartilage have been conducted using normal cartilage. Current research suggests that inflamed or abnormal joints do not exhibit the detrimental effects seen in normal joints when corticosteroid is administered, potentially explaining some discrepancies seen in experimental studies conducted on normal tissues compared to clinical impressions.

It is well documented that corticosteroids inhibit the arachidonic acid cascade by blocking phospholipase A2 and that they are selective COX-2 inhibitors. The selective COX-2 inhibition, and low incidence of side effects, may be one of the reasons this class of medication is so useful in the horse. The use of corticosteroids for joint disease often brings up three main questions: which preparation to use, at what dose, and the appropriate rest period.

Currently, three main corticosteroid preparations are available to the equine clinician: methylprednisolone acetate (Depo-Medrol), triamcinolone acetonide (Vetalog), and compounded betamethasone sodium phosphate and betamethasone acetate (Celestone Soluspan, formerly Betavet) (Table 84-4). Compounded betamethasone has been difficult to obtain commercially in the United States, but it remains available in other countries. As a result, it has been compounded by various pharmacies; however, significant problems have resulted from the use of some of these formulations.

Experimental studies have provided a relatively good comparison of these three products and found that they are not equivalent. The three preparations were tested using a relatively similar osteochondral fragment model. Results of this work indicated that the most beneficial effects were seen with triamcinolone, and some protective effects were associated with this preparation. Methylprednisolone did have beneficial effects, but detrimental effects on the articular cartilage were also demonstrated. Compounded betamethasone had no measured effects, which suggests that this

bid, twice daily; IM, intramuscular; IV, intravenous; PO, by mouth.
preparation has a less potent effect on joint tissues compared to triamcinolone and methylprednisolone. Compounded betamethasone might not have caused significant improvement because the newly developed experimental model might not have elicited sufficient lameness to evaluate a difference. These in vivo studies coupled with in vitro work have fueled the recommendation to use triamcinolone, especially in high-motion joints.

Recent research has also focused on low-dose corticosteroid administration for the treatment of equine joint disease. It appears to take about a 10-fold change in concentration to alter in vivo effects of corticosteroids. As an example, joint concentrations between 1 mg and 10 mg of triamcinolone or between 20 mg and 200 mg of methylprednisolone would respond in a relatively similar manner. However, in vitro studies have indicated that lower concentrations of these corticosteroids might not inhibit the catabolic pathways driving joint disease.\(^9\)\(^8\)\(^9\) The currently recommended doses (see Table 84-4) appear to be within an acceptable range given in published information.

Corticosteroids combined with hyaluronan are very commonly administered. This combination is based on limited scientific evidence but good clinical responses. Combination treatment was supported by 50% to 80% of recently polled equine practitioners, reinforcing the favorable clinical response.\(^9\)\(^9\)

The exercise or rest period following treatment with IA corticosteroids is also somewhat controversial. The controversy is based on the ability of some corticosteroids to transiently decrease the anabolic metabolism of chondrocytes and potentially blunt the normal metabolic responses to exercise. Although this is a concern, it is most likely overstated. A decrease in chondrocyte anabolic rate has not been proved to be detrimental. Furthermore, studies have not identified gross or histologic lesions subsequent to IA corticosteroid administration and exercise; however, changes in biochemical and biomechanical parameters have been identified. Changes induced by methylprednisolone have been noted to last for more than 21 days, and this information has influenced exercise recommendations for all other corticosteroids. Anecdotal recommendations for rest periods after IA corticosteroid injection vary widely from immediate return to work to more than 30 days of rest. Even a relatively aggressive protocol, involving a high dose of corticosteroids repeated at 14 days along with concurrent strenuous exercise, has failed to demonstrate definitive detrimental effects.\(^9\)\(^8\)\(^9\) Thus, a rest period might not be absolutely necessary. Anecdotal clinical impression does suggest that confinement to a box stall and run for 7 to 10 days, with a slow return to full work in the subsequent week, can prolong the duration of action following injection, but it does not appear to alter the effect of the treatment.

Some consideration should be given to the reported incidence of corticosteroid-induced laminitis; however, no direct association has been proved. It has been suggested that the total body dose of triamcinolone should not exceed 18 mg, methylprednisolone should not exceed 200 mg, and compounded betamethasone should not exceed 30 mg. These numbers are based on some fact and some fiction, but one of the main goals is to eliminate corticosteroid-induced laminitis. A recent study with long-term follow-up on 205 clinical cases of joint injections using either 40 mg or 80 mg of triamcinolone acetonide found that the incidence of laminitis was effectively 0.5%.\(^10\) Because it is not possible to have a consistent model of laminitis following corticosteroid injection, we must rely on clinical reports and anecdotal suggestions for dosing regimens.

### Hyaluronan

Hyaluronan (HA) is a normal and necessary component of synovial fluid and proteoglycan aggregates (aggrecan) (see Fig. 83-10). Based mainly on in vitro work, both the concentration and molecular weight (degree of polymerization) appear to be important in the normal function of HA. Although the exact mechanism through which endogenous or exogenous HA exhibits an effect is not known, additional effects of exogenous HA administration have been documented to include anti-inflammatory activity such as inhibition of chemotaxis, inhibition of phagocytosis of granulocytes and macrophages, and reduction in the stimulation, proliferation, and migration of lymphocytes. Hyaluronan has also been shown to decrease the formation and release of prostaglandins from macrophages and to scavenge oxygen-derived free radicals in a dose-dependent manner.\(^10\) Researchers also hypothesize that exogenous administration of HA increases the synthesis of high molecular weight hyaluronate by the synoviocytes, a theory that is
yet to be definitively proved. In addition, some questions exist about the molecular weight requirement for effectiveness of exogenous HA.

Previous research has suggested that molecular mass less than 500 kDa has little effect, whereas HA with a larger molecular mass demonstrates a dose-dependent response. Other studies have failed to correlate molecular mass to outcome parameters. Summarizing the current literature, it appears that some basal molecular mass is needed for effectiveness. The author therefore uses products with molecular mass greater than 500 kDa and selects products with yet higher molecular mass based more on economic consideration of the client (Table 84-5).

Crossed-linked exogenous HA has been introduced in an attempt to improve viscosupplementation of joints. Briefly, viscosupplementation refers to the injection of HA or its derivative in an attempt to return the elasticity and viscosity of the synovial fluid to normal or higher levels. Cross-linked HA has been developed as an improvement to other synthetic HA. Because its rheologic properties are increased, it has a longer retention time in the synovial space and appears to be more resistant to free radicals. Hylan G-F20 (Synvisc), a cross-linked HA with a molecular mass on average greater than 6 MDa, has demonstrated favorable results in large multicenter human clinical studies, showing effectiveness as a nonsteroidal medication. An experimental study conducted in the horse failed to show beneficial effects of hylan, but it does cite the difference in acute experimental synovitis compared to the more chronic OA (in the human trial) as one possible explanation for the study outcome. The authors also mention that the severity of the model may have been too harsh to observe a significant treatment effect. Further work on case selection for viscosupplementation (cross-linked HAs) is needed.

The dosage of conventional HA (0, 1, 10, 20, and 40 mg per joint) has been tested using an equine OA model. This study demonstrated that a dose of 20 mg per joint was needed to demonstrate improvement in degree of lameness measured using a force plate. Dose-frequency studies are based on work in human clinical patients, suggesting that at least 3 doses are required (administered one week apart) to see significant effects in clinical parameters of pain and effusion. The current recommended equine HA treatment protocol is 20 mg of HA once a week for 3 weeks. Clinical equine reports have generally supported the use of HA, but many of these published evaluations have been subjective.

and the definitions of criteria for successful treatment are absent. It appears that HA may be more effective when used in cases of mild synovitis or capsulitis and not as effective in severe synovitis or capsulitis and chronic OA.104

The use of intravenous (IV) HA in the treatment of joint disease is very common. An experimental study documented improvement in clinical lameness and synovial membrane histology, as well as better synovial fluid parameters such as lower PGE2 and total protein levels in a carpal chip model.105 These improvements were seen 42 days following the last of three treatments (40 mg) that were given 1 week apart.

Research to elucidate the mechanism of action for IV HA has been conducted, although relatively few answers have been found. A recent survey of 20 equine practitioners did not reflect an overwhelming usefulness of IV HA; however, case selection or objective outcome parameters were not clearly defined.10 From both scientific and anecdotal reports, it appears that the use of IV HA in cases of acute synovitis could yield a better chance for success than in cases of chronic OA, where significant cartilage loss is present.

The prophylactic use of IV HA has also been studied in both Quarter and Thoroughbred racehorses. The Quarter Horse study enrolled 140 horses; subjects received either IV saline or HA every 2 weeks for the duration of the 9-month study.106 HA-treated horses tended to race longer before requiring the first joint injection and to have a better speed index, higher average number of starts, and more money earned compared to placebo-treated horses. A similar study has been conducted in Thoroughbred racehorses to alleviate confounding variables introduced with the multiple trainers used in the Quarter Horse study, but data on performance outcomes is not yet available. Anecdotal reports from trainers in various equine disciplines have been positive regarding the prophylactic use of IV HA.

### Polysulfated Polysaccharides

Polysulfated polysaccharides include polysulfated glycosaminoglycan (PSGAG; Adequan), GAG peptide complex (Rumalon), and pentosan polysulfate Cartrophen Vet; Pentequin). These drugs have been referred to as exhibiting chondroprotective effects or, by more recent definitions, are slow-acting disease-modifying osteoarthritic drugs (SAMOADs). Such agents are meant to prevent, retard, or reverse the morphologic cartilaginous lesion of OA.

PSGAG is made from bovine lung and trachea extracts containing mainly chondroitin sulfate. Numerous equine studies have been carried out in vitro and in vivo using PSGAG and have had contradictory results. Some studies have shown PSGAG to inhibit many of the key enzymes or cytokines involved in OA including IL-1, matrix metalloproteinases (MMPs), and PGE2, as well as affecting proteoglycan synthesis and degradation. Because the testing systems, duration of experiments, and dosages varied from study to study, direct comparisons are difficult. The precise mechanisms of action of PSGAG are uncertain and the interaction of PSGAG with cytokines involved in joint disease has not been well defined.

Some of the earliest work involving IA PSGAG in the horse investigated the effects of administering 250 mg biweekly for 3 weeks in clinical cases. This study and others using models of acute synovitis have shown improvements in clinical disease parameters following PSGAG treatment. One study also looked at cartilage histology, observing improvement in chondrocyte morphology. The same authors, using a similar model, also tested PSGAG via an IM route with less impressive results.102 In a group of ponies with experimentally induced osteochondral lesions, IA PSGAG (250 mg once a week for 5 weeks) significantly improved clinical lameness, radiographic progression of OA, and joint capsule parameters compared with untreated ponies. However, PSGAG also reduced the endogenous repair of the cartilaginous lesions.105 Therefore, care should be taken when using PSGAG in cases where significant cartilage lesions exist on weight-bearing surfaces.

In an experimental study, IM PSGAG administered every 4th day for 28 days, starting 14 days following OA induction, demonstrated some improvement in clinical lameness 56 days after initiation of treatment.107 Although PSGAG-treated horses did show biochemical improvements compared to placebo-treated horses, overall more impressive improvements were observed with shock wave treatment of the affected joint (see "Extracorporeal Shock Wave Therapy").

A survey104 to assess the perceived efficacy of PSGAG by 1522 equine practitioners was published in 1996. Practitioners treating Thoroughbred racehorses gave the highest efficacy scores, and practitioners treating pleasure horses gave the lowest efficacy scores. PSGAG was considered more effective than sodium hyaluronate for the treatment of subacute OA and less effective for idiopathic joint effusion and acute synovitis. The authors of the survey concluded that the efficacy of PSGAG for incipient and chronic forms of OA is comparable to that of sodium hyaluronate.

Important information has been published indicating that a lower bacterial inoculation is needed to establish septic arthritis when PSGAG is administered IA. This result is abolished with the addition of 125 mg amikacin with the PSGAG treatment. Therefore, administration of amikacin with PSGAG administered IA is strongly recommended.

Like PSGAG, pentosan polysulfate (PPS) is a heparinoid compound, but it is unique in that it is derived from beechwood hemicellulose instead of animal or bacterial sources as with PSGAGs. These products have been administered mainly in horses in Australia, although efficacy reports have been anecdotal. To the author’s knowledge, sodium pentosan polysulfate has been used only parenterally in horses. Although a form has been complexed with a calcium salt and tested in other species, the results indicate that pentosan appears to be bioavailable following oral administration. Clinical studies in dogs and people with OA have shown convincing evidence of clinical efficacy.108 In the horse, an unpublished study using an experimental model of OA has shown favorable results.109 In this model, parenteral PPS showed significant improvement in reducing articular cartilage fibrillation and a strong trend for overall improvement in the histologic appearance of cartilage. Furthermore, most parameters showed numerical improvements (lameness, joint flexion, synovial fluid total protein, synovial fluid collagen degradation products, and aggrecan synthesis), although statistical significance of greater than 95% was not obtained.

Clinically, PPS could be used to treat horses with mild or early-stage OA, particularly with multiple joint involvement, because it is a systemic therapy. At this time, a dose of
3 mg/kg IM once weekly for 4 weeks is recommended for treatment of equine OA.

**Oral Joint Supplements**

A vast number of different oral supplements are available for the horse. Many of these work on the premise of providing building blocks of molecules that are integral in the articular cartilage or joint fluid. Although the formulation, concentration, and source of the products differ widely, most contain chondroitin sulfate, glucosamine, or hyaluronan, or some combination of these. Chondroitin sulfate has been assessed using radioisotope tracking and shown to be absorbed through the gastrointestinal tract, but it is thought to be in a smaller monomeric form compared to the ingested molecule. Glucosamine is even more bioavailable when compared to chondroitin sulfate.109-111

A study was conducted to document absorption specifically in the horse, but how these levels relate to clinically therapeutic levels is yet to be determined.110 Double-blinded controlled studies in humans have indicated that these substances are efficacious in the treatment of joint disease.114-117 Unfortunately, only limited, poorly controlled equine clinical studies have been performed to date, but anecdotal reports and in vitro tests are favorable for the use of glucosamine and chondroitin sulfate.118

Oral hyaluronan products are relatively new on the market and have been tested less compared to chondroitin sulfate or glucosamine. However, a controlled experimental in vivo trial comparing IV Legend and Conquer, an oral hyaluronan, is under way. An interesting report in the human literature compared the label ingredient with the independent testing of the products and found little correlation to label claim and content or price and content. This potentially emphasizes the use of trusted brands that have at least undergone some testing.

**Extracorporeal Shock Wave Therapy**

Recent experimental evidence and anecdotal clinical impressions of extracorporeal shock wave therapy (ESWT) for the treatment of OA have been reported.119-121 Unpublished clinical studies in the dog have shown promising results, as have anecdotal reports of treating shoulder, pastern, and coffin joint OA in horses.127 An equine-specific-controlled experimental OA study has been completed comparing ESWT to PSGAG and sham treatments. The study used an established short-term (70 days) OA model where an osteochondral fragment was created at time zero and treatments were initiated 14 days later.127 IM PSGAG treatment was administered every 4 days for 28 days. ESWT was administered on days 14 and 28 using a VersaTron (High Medical Technologies, Lengwil, Switzerland) 12 mm probe, and a sham shockwave procedure was performed on the control horses on days 14 and 28. In the ESWT group, 2000 shock waves at the E4 energy level were administered on study day 14 and 1500 shock waves at the E6 level on study day 28. The energy was delivered mainly to the middle carpal joint capsule attachment, but some energy (approximately 20%) was delivered to the area of fragmentation. Significant improvement in clinical lameness, decreased synovial fluid total protein (as a marker of synovitis), and less GAG release into the bloodstream were observed with ESWT compared to both control and PSGAG-treated horses. These results appear to show promise for this type of therapy for use in localized joint disease in horses, although clinical studies are still needed.

**Challenges of Medical Management in Equine Joint Disease**

Some of the considerations in treating equine joint disease have been presented in this chapter. Challenges that equine clinicians face are numerous, but the rapid evolution of knowledge of joint disease pathophysiology, the relative lack of specific equine research, economic considerations of the owner, and rules imposed by governing bodies of sanctioned equine events pose a unique set of challenges. More specifically, the pathophysiology of joint disease is extremely complex; the multifactorial nature of the disease makes it challenging to study, and at best it is only partly understood in any species.122,123 Even with the greatest understanding of the disease being in people, human physicians do not agree upon a course of treatment based on joint affected, stage of disease progression, or age of the patient. Further removed is the equine practitioner, who is often making therapeutic decisions based on extrapolated data from people, a comparison that is not always justifiable.

The lack of specific equine research often drives the need to extrapolate from other species on the class of substance to use, specific compound within a class (such as specific corticosteroid), dose, frequency of administration, or whether a combination of medications should be employed. The equine clinician is often left to make a plan based on anecdotal information rather than substantial evidence showing safety or efficacy of a specific regimen. Advances in equine-specific studies are occurring, thus confirming or refuting many anecdotal or uncontrolled published studies although, as expected, much work is left to be completed.

Other factors do play a real role in defining a therapeutic plan, but some of them have little to do with the defined treatment goals. Economic consideration and medication rules governing many sanctioned equine events are just two such examples. The coordination of all of the presented factors and issues into a sound, effective therapeutic plan are what makes treatment of equine joint disease challenging. Through an understanding of the historic and current literature, anecdotal information, and up-to-date rules pertinent to equine events, advancements can be realized in the treatment of equine joint disease.

**Future Therapies**

Since the 1990s, research has led to a greater understanding of joint disease pathophysiology and identification of major mediators driving the disease process. Also, the identification of naturally occurring antagonists or synthetic analogs with the ability to block these degenerative mediators has been realized. Numerous novel medical treatments are being tested in vivo after successful in vitro trials.124,125 Furthermore, in the long term, the field of tissue engineering is burgeoning with the promise of being able to recreate organ systems.126 Realistically, in the short term, the
subdiscipline of cartilage engineering is most likely to make
the biggest impact on the treatment of equine joint disease
and is an active area of research at several equine orthopedic
research facilities.

Treatment of generalized OA using novel methods of
administering antiarthritic therapeutic proteins will most
likely be the first advance that changes the future of treating
equine joint disease.126-128 Given that the inhibition of IL-1
likely be the first advance that changes the future of treating
and is an active area of research at several equine orthopedic
the biggest impact on the treatment of equine joint disease
osteoarthritis.130,131

Advancement in delivering genes or recombinant
techniques to improve cartilage healing and treatment of
this technology is being used in combination with surgical
delivery of the genetic information to overproduce
injection of a nonpathogenic virus. This virus was engi-
eered to deliver the genetic information to overproduce
equine IL-1Ra protein within joint tissues without causing
effects on the cell. In this study, the ability to decrease
clinical lameness and slow the progression of induced
disease was more profound than any other medication
tested (including corticosteroids, PSGAG, PPS, HA, or
ECSWT). Advancement in delivering genes or recombinant
proteins to specific target cells and the ability to turn on and
off the protein production is being realized. Furthermore,
this technology is being used in combination with surgical
techniques to improve cartilage healing and treatment of
osteoarthritis.180,181

CHAPTER 85

Arthrodese Techniques
Jörg A. Auer

It is every surgeon’s goal to maintain or reestablish joint integrity to allow optimal function after treatment and subsequent healing of an injury. Unfortunately, in many instances this is not attainable, and degenerative changes limit the horse's use as an athlete or a pleasure animal.

However, in some joint disorders arthrodesis is an option to maintain a useful horse despite sacrificing a joint. By definition, arthrodesis involves surgical fixation of a joint by a procedure designed to promote fusion of the joint surfaces. Ankylosis involves achievement of immobility and consolidation of a joint damaged by disease, injury, or a surgical procedure. Therefore, an arthrodesis may be thought of as a type of ankylosis.

In most cases, surgical arthrodesis is carried out to salvage valuable breeding stock. However, certain joints can be fused without unduly compromising the animal’s performance.

GENERAL GUIDELINES

The articular cartilage of opposing bones should be removed for achievement of an effective arthrodesis within the shortest time. Persistence of cartilage between the bone ends delays bone union. Immobility of a joint with persistent articular cartilage results in malnutrition of the cartilage and its eventual degeneration. This is a very slow process, and islands of articular cartilage can persist between bone bridges across a joint for several years. However, removing minimal cartilage, by drilling across a joint surface, for example, can result in a joint with minimal movement and produce a functional arthrodesis with relief of pain symptoms. This procedure can be performed in the small tarsal articulations. As a general rule, such cartilage as possible should be removed, allowing maximum bone-on-bone contact.

Fusion of the joint is facilitated by drilling several holes of 2.5 to 3 mm in diameter across the dense subchondral bone plate of each of the opposing bone ends. This type of osteostixis promotes ingrowth of blood vessels across the bone plate and hastens fusion. Incorporation of a cancellous bone graft, tricalcium phosphate granules, or injectable biodegradable bone cement or hydrogel enhances fusion of the joint as well.

Arthrodesis requires joint immobility, and this is accomplished by means of multiple screws placed in lag fashion, application of a bone plate, or implantation of a transarticular Bagby basket. The principal techniques used for arthrodesis of the distal and proximal interphalangeal joints, metacarpophalangeal joint, and carpal and tarsal region are discussed in detail in this chapter. Additionally,
124. Chikanza I, Fernandes L: Novel strategies for the treatment of osteoarthrosis promotes ingrowth of blood vessels across the bone graft, tricalcium phosphate granules, or injectable bone plate and hastens fusion. Incorporation of a cancellous bone bridge across a joint for several years. However, removing minimal cartilage, by drilling across a joint surface, for example, can result in a joint with minimal movement and produce a functional arthrodesis with relief of pain symptoms. This procedure can be performed in the small tarsal articulations. As a general rule, as much cartilage as possible should be removed, allowing maximum bone-on-bone contact.

Fusion of the joint is facilitated by drilling several holes of 2.5 to 3 mm in diameter across the dense subchondral bone plate of each of the opposing bone ends. This type of osteostixis promotes ingrowth of blood vessels across the bone plate and hastens fusion. Incorporation of a cancellous bone graft, tricalcium phosphate granules, or injectable biodegradable bone cement or hydrogel enhances fusion of the joint as well. Arthrodesis requires joint immobility, and this is accomplished by means of multiple screws placed in lag fashion, application of a bone plate, or implantation of a transarticular Bagby basket. The principal techniques used for arthrodesis of the distal and proximal interphalangeal joints, metacarpophalangeal joint, and carpal and tarsal region are discussed in detail in this chapter. Additionally,
the arthrodesis technique applied in the scapulohumeral joint is briefly discussed.

DISTAL INTERPHALANGEAL JOINT ARTHRODESIS

Indications
Disorders that are not responsive to massive anti-inflammatory therapy and neurectomy might be candidates for distal interphalangeal (DIP) joint arthrodesis. The indications include advanced osteoarthritis and luxation of the DIP joint after rupture of the deep digital flexor tendon at the level of the distal sesamoid bone. This surgical intervention is a salvage procedure and does not permit the patient to assume any form of athletic competition. However, the horse might be useful for breeding.

Surgical Techniques
For this arthrodesis, two surgical approaches are necessary. Through a dorsal approach to the DIP joint, as much articular cartilage as possible is removed and the implants are inserted through a palmar approach to the proximal and palmar aspect of the middle phalanx. An 8-cm semi-circumferential horizontal skin incision is made 1 cm proximal and parallel to the coronary band, centered over the midline of the foot. The incision is extended through the common digital extensor tendon into the dorsal pouch of the DIP joint. The incision is extended through the joint capsule and the collateral ligaments until the joint can be subluxated. Approximately 70% of the articular cartilage can be removed with a curet through this approach, but the distal sesamoid bone and the palmar aspect of the middle phalanx cannot be accessed for cartilage removal.

The palmar approach involves an 8-cm skin incision parallel to the long axis of the limb in the median plane centered over the proximal interphalangeal (PIP) joint. The incision is extended into the digital tendon sheath, where the deep digital flexor tendon is transected and reflected. Three stab incisions through the distal sesamoidean ligament provide access to the proximal palmar rim of the middle phalanx.

While maintaining the DIP joint in reduction, the first thread hole is prepared under fluoroscopic control across the middle phalanx in a distodorsal direction into the distal phalanx. The thread hole across the middle phalanx is enlarged to a glide hole, with the joint opened to prevent inadvertent enlargement of part of the thread hole in the distal phalanx. Then two more glide holes across the middle phalanx are made parallel to the first one. The center hole is finished using routine lag screw technique, and a 5.5-mm cortex screw of correct length is inserted and solidly tightened. Care should be taken to make sure that the screw does not impinge on the blind end of the thread hole, because this would prevent effective compression of the joint surface. The other two 5.5-mm cortex screws are implanted using routine technique (Fig. 85-1). If a cancellous bone graft or an alternate osteoinductive material (see Chapter 82) is used, the screws may be loosened temporarily so that the material can be placed through the dorsal aspect of the joint.

The dorsal incision is closed in three layers: extensor tendon and joint capsule, subcutaneous tissue, and skin. Although an attempt should be made to suture the ends of the deep digital flexor tendon with interrupted sutures of no. 0 polydioxanone, the tendon ends often retract, making accurate anatomic reconstruction impossible. The palmar incision is closed in two layers: tendon sheath and subcutaneous tissues in one layer followed by closure of the skin layer. The limb is placed into a half-limb cast for 3 months, ideally with only one cast change. Routine anti-inflammatory therapy and antibiotic prophylaxis are used.

In one horse that suffered from nonresponsive progressive arthritis of the DIP joint, this technique resulted in solid fusion. The horse was able to ambulate with a mechanical lameness but was pain free for more than a year.

PROXIMAL INTERPHALANGEAL JOINT ARTHRODESIS

Indications
Indications for arthrodesis of the PIP joint include osteoarthritis (high ring-bone), comminuted fractures of the proximal or middle phalanx, and luxation or subluxation of the PIP joint. Fractures entering the PIP joint through either the proximal or the middle phalanx often result in osteoarthritis or subluxation.

Because of the low-motion and high-load nature of this joint and the lack of interdigitation, attempts to manage the majority of common conditions of the PIP joint by methods other than arthrodesis usually fail to provide long-term success. Therefore, arthrodesis is often performed as part of the definitive treatment of the fracture. In comminuted fractures of the proximal phalanx, the middle phalanx serves as the distal fragment, achieving additional stability for the fixation. Conversely, the proximal phalanx can serve as the proximal fragment in comminuted middle phalanx fractures.

Recent Developments
Over the years, a variety of techniques have been advocated for PIP joint arthrodesis. The technique most often applied since the 1980s used three transarticular cortex screws placed in lag fashion in a parallel or diverging pattern. This technique has several disadvantages. The almost linear alignment of the screws in the frontal plane provide minimal stability, especially at the dorsal aspect of the joint. This has resulted in patient discomfort because of excessive...
new bone formation that has impinged on the extensor tendon or the coffin joint, or both. The screw tip can protrude at the middle aspect of the palmar or plantar cortex of the middle phalanx, which can interfere with the dynamics of the distal sesamoid bone. The bone can fail at the dorsal aspect of the proximal phalanx distal to the glide holes because of the acute angle at which the screws are inserted. The period of external coaptation is prolonged: 6 to 8 weeks postoperatively in cast, which is advocated by most surgeons. Therefore, new techniques were needed and have been developed.

A recent in vitro study compared interfragmentary cortex screws applied in lag fashion in fore- and hindlimbs; three parallel 4.5-mm cortex screws were compared to two parallel 5.5-mm cortex screws in three-point bending to failure. The bending moments were greater in the forelimbs than in the hindlimbs. The difference between the two techniques was not statistically significant. However, more 4.5-mm cortex screws failed than 5.5-mm.

An arthrodesis technique using an axial plate in conjunction with two abaxial transarticular lag screws was also tested in vitro. A substantial increase in stability across the dorsal aspect of the PIP joint was recorded in addition to a significantly longer fatigue life compared to the method using three transarticular screws. Clinical results gained on horses suffering from osteoarthritis, subluxations, and some stable middle phalanx fractures confirmed the in vitro results.

Postoperatively, the patients were more comfortable on the limb and the cast was removed earlier compared to patients treated with the three parallel 5.5-mm cortex screws. No difference was found in the number of horses returning to soundness. Based on these studies, the author recommends the plate technique.

Surgical Techniques
Preparation
The joint is approached through an inverted-T skin incision that begins just distal to the level of the metacarpophalangeal (MCP) or the metatarsophalangeal (MTP) joint and ends at a horizontal skin incision made 1.5 cm proximal to the coronary band. The horizontal incision extends 4 cm on either side of the midline. The subcutaneous tissue is separated sharply down to the common digital extensor tendon. The two triangular skin flaps are dissected free from the common digital extensor tendon with the help of scissors and sutured to the intact skin on either side of the incision.

The common digital extensor tendon is transected with an inverted V-shaped tenotomy at the level of the insertion of the extensor branches of the suspensory apparatus (Fig. 85-2). The proximal tendon stump is reflected proximally using scissors, taking care to spare the attachments of the extensor branches of the suspensory ligament. The distal tendon stump is sharply incised along its lateral and medial sides and reflected distally, exposing the PIP joint.

The dorsal attachments of the PIP joint capsule are sharply incised parallel to the joint surface, the collateral ligaments are transected, and the joint is disarticulated. As much cartilage as possible is removed from both articular surfaces with a curet. By removing the articular cartilage layers, the radii of the two opposing bones are altered.
Arthrodesis

The preferred technique for arthrodesis of the proximal interphalangeal joint involves the application of a three-hole narrow limited-contact dynamic compression plate (LC-DCP) in conjunction with two additional transarticular cortex screws \(^\text{10}\) (Fig. 85-4). The plate is temporarily placed axially over the joint, with the single hole positioned at the proximal and dorsal aspect of the middle phalanx. This permits the size of the screw heads to be taken into account while the location of the two holes for the transarticular lag screws are marked on the distal aspect of the proximal phalanx.

With the joint opened, drilling of the 5.5-mm glide hole for the first lag screw is started perpendicular to the bone surface, followed by a gradual redirection of the drill to the desired oblique orientation. Because the middle phalanx is wider than the proximal phalanx, the drill holes are prepared in slightly diverging directions. Drilling is continued until the drill bit enters the joint to ensure lag effect without drilling into the palmar and proximal aspect of the middle phalanx. The hole should enter the joint midway between the dorsal and palmar or plantar cortices. The same procedure is repeated on the other side for the second lag screw. The 3.2-mm drill bit, protected by the corresponding drill guide, is used to prepare several osteostixis holes across the subchondral bone plate of the middle and proximal phalanx. By waiting with this procedure until the two glide holes have been prepared, the osteostixis holes can be placed so that they do not interfere with the glide holes.

With the joint remaining open and using the 4.0-mm drill bit placed through the neutral drill guide, a thread hole is prepared parallel to the joint surface in the proximal aspect of the middle phalanx for placement of the distal plate screw. By positioning the plate proximally, interference between the extensor process of the distal phalanx and the distal end of the plate is prevented. Additionally, the risk of inadvertent injury to the distal sesamoid bone at the palmar or planter aspect of the middle phalanx is reduced. A 5.5-mm cortex screw of correct length is inserted through the distal single hole in the plate and into the middle phalanx, but it is only partially tightened. The joint is closed to its normal anatomic position.

The countersink is used to prepare depressions in the bone for the heads of the lag screws. Care is taken to work predominantly on the proximal rim. The plate is displaced proximally, and with the help of the load drill guide the thread hole is drilled through the middle plate hole perpendicular to the long axis of the proximal phalanx. The selected 5.5-mm cortex screw is inserted but not fully tightened. The thread hole for one of the lag screws is finished and the screw is inserted and tightened. The second screw is implanted in the same manner. The two plate screws are now tightened as well, bringing about transarticular compression. Finally, the most proximal screw is inserted in the neutral position parallel to the center screw. Only the dorsal cortex of the proximal phalanx is used for this screw (Fig. 85-5).

This technique has a biomechanical advantage over a single plate: it provides compression across the entire joint because the tensile forces, which develop at the palmar aspect of the joint and are caused by the plate, are neutralized by the two oblique transarticular lag screws. It has a similar advantage over the three-screw technique because the dorsal joint instability seen with that technique is obviated by the plate.

Closure and Aftercare

Closure of the V plasty of the tendon is accomplished with no. 1 polydioxanone suture using a simple continuous pattern, and the skin is apposed using a combination of no. 0 polypropylene (Prolene) and skin staples. A standard distal limb cast is applied for the immediate postoperative period to protect the fixation during recovery and, most importantly, to support healing of the soft tissues. The cast is removed at about 2 weeks, and every other skin suture is taken out at that time, with the patient standing. The limb is protected with a bandage, and the remaining sutures are removed at the next bandage change. The horse is discharged from the clinic about 3 weeks postoperatively. Owners are advised to limit exercise to hand-walking for the next 3 months.

Discussion

When treating fractures of the middle or proximal phalanx with an arthrodesis technique, it may be advisable to apply two plates, one dorsomedially and one dorsolaterally, once the bone has been reconstructed with strategically placed lag screws \(^\text{16,19}\) (Fig. 85-6). Care is taken to prevent interference of the interfragmentary lag screw heads with the plates. Therefore, 3.5-mm cortex screws are often used because they permit the screw heads to be buried within the cortex.

A biomechanical in vitro study compared two seven-hole, 3.5-mm broad DCPs with two five-hole 4.5-mm narrow DCPs. The DCPs were placed dorsomedially and dorsolaterally, respectively. No significant difference was detected...
either in composite stiffness or maximal bending moment between the two fixation techniques. Therefore, either plate size could be used for arthrodesis of the PIP after fractures to the pastern.

The closure of soft tissues after this technique involves a simple continuous suture of the tenotomy incision along the reflected tendon stumps, and an additional simple continuous pattern of 2-0 or 3-0 absorbable monofilament suture material placed subcutaneously, intradermally, or both, followed by skin closure. A cast is applied after all arthrodeses for the initial postoperative period. When a cast is used after fracture reconstruction, the time period will vary depending on stability of the repair and healing.

Long-term follow-up results after arthrodeses of the proximal interphalangeal joint from one study reported success rates of 67% and 80% in the forelimbs and hindlimbs, respectively. Another retrospective study on 39 proximal interphalangeal joint arthrodeses performed using two parallel 5.5-mm cortex screws applied in lag fashion on 34 horses revealed a success rate of 85% in the forelimbs and 89% in hindlimbs. The increased bending moment recorded in the front limbs compared to the rear limbs by Watt and colleagues could explain the clinical observation that hindlimb arthrodeses have a better prognosis for return to soundness.

Figure 85-5. A, Immediate postoperative dorsopalmar and lateromedial radiographs of a PIP joint arthrodesis in a 2-year-old Thoroughbred filly with a proximal palmar fracture of the middle phalanx. The arthrodesis was accomplished with a three-hole narrow DCP and two 5.5-mm cortex screws. The plate used two loaded bicortical 5.5-mm screws and a single unicortical 4.5-mm screw in the proximal hole. The two transarticular 5.5-mm cortex screws were inserted in lag fashion to provide plantar compression. The arrow points to the palmar fragment of the middle phalanx. Note the slightly radiolucent osteositis holes in the distal aspect of the proximal phalanx. B, The 11-month follow-up dorsopalmar and lateromedial radiographs show complete fusion of the joint, with negligible periarticular new bone formation. (Courtesy J. Watkins, Texas A&M University.)

Figure 85-6. A, Dorsopalmar radiograph of a comminuted proximal phalanx fracture. B, The fracture has been repaired with several lag screws and a six-hole narrow DCP as a neutralization plate. To gain stability and to prevent osteoarthritis in the proximal interphalangeal joint, an arthrodesis was performed. Two cortex screws were placed transarticularly in lag fashion. A second plate could have been applied to the dorsomedial aspect of the proximal and middle phalanx for even greater stability. In this case, six 5.5-mm and five 4.5-mm screws were used.

ARTRODESIS TECHNIQUES

METACARPOPHALANGEAL OR METATARSOPHALANGEAL JOINT ARTHRODESIS Indications

MCP or MTP joint arthrodesis is performed for breakdown injuries of the suspensory apparatus. This injury occurs almost exclusively in the forelimbs of Thoroughbred racehorses, although it can be suffered by any horse running at high speed. Fatigue of the digit flexor ligaments and flexor muscles supporting the fetlock and digit leads to higher stresses in all components of the suspensory apparatus and permits development of the injury. Comminuted proximal phalanx fractures, advanced osteoarthritis, and severe flexural deformities of that region represent other indications for the arthrodesis. In flexural deformities, an osteotomy might be needed to achieve an acceptable joint angle before arthrodesis.
The major physical finding is dorsiflexion or hyper-extension (dropping) of the fetlock joint as the horse attempts to bear weight. Many horses become anxious or even frantic as they attempt to control the injured limb. The disruption can occur as a result of fracture of both proximal sesamoid bones in the injured limb or, less often, rupture of the distal sesamoidean ligaments of the two suspensory ligament branches.

Breakdown of the suspensory apparatus should always be considered a career-ending injury. Because of the massive trauma that occurs with this injury, a myriad of complications is expected. It is therefore important to explain the situation to the owner so that an informed decision can be made concerning treatment. Most horses can be saved as pasture-sound or breeding animals, but treatment is often prolonged and expensive, despite the therapeutic approach selected.

**Surgical Techniques**

**Dorsal Plate Technique**

The most frequently applied technique for MCP or MTP arthrodesis involves implanting a dorsal plate and creating a tension band on the palmar aspect (Fig. 85-7). Dorsal plating without a tension band on the palmar aspect of the fetlock usually results in failure, because the plate cycles in bending on the joint’s dorsal surface and eventually breaks. The different techniques used to create the tension band depend on the type of breakdown injury.

A straight skin incision is made between the common and lateral digital extensor tendons, extending from the proximal aspect of the third metacarpus or third metatarsus (MCIII or MTIII) to the proximal interphalangeal joint. The incision is carried through the periosteum.

A 5-cm sagittal strip of the proximal phalanx is denuded of periosteum. The joint capsule of the MCP or MTP joint is transected parallel to the articular surface. Transection of the lateral collateral ligament, as well as the lateral metacarpoesamoidean or metatarsoesamoidean ligament, allows disarticulation of the joint and removal of all articular cartilage from the proximal phalanx, the distal MCIII or MTIII, and the proximal sesamoid bones.

The cartilage is removed with a curette, and multiple osteostixis holes are drilled across the subchondral bone plates of all of the bones. With an osteotome, the proximal dorsal end of the proximal phalanx and the intermediate ridge of the distal MCIII or MTIII are contoured to accept a 14-hole, 5.5 LC-DCP (see Fig. 81-17), which is slightly bent at an angle of about 8 to 10 degrees. Because compression can be applied on either side of all plate holes of the LC-DCP (dynamic compression unit [DCU] architecture), placement of the plate is not critical. The plate is applied with the three or four most distal screws inserted in neutral position into the proximal phalanx. The hole adjacent to the joint should at this point be left without a screw.

With an intact suspensory apparatus, one 5.5-mm cortex screw is placed in lag fashion from the dorsal aspect of the distal MCIII or MTIII into each proximal sesamoid bone. For that procedure, the joint is maintained in a slightly flexed position. Using the tension device, the plate is tightened across the joint, and two screws are inserted in a neutral position through proximal plate holes into the MCIII or MTIII. Forcing the MCP or MTP joint into a slightly extended position tightens the distal sesamoidean ligament, which accepts the tension band function and protects the dorsally applied plate.

The tension device is removed, and the remaining plate holes are filled with screws except the two screws immediately adjacent to the joint. These screws are implanted transarticularly in lag fashion. Care must be taken to direct the screws so that they do not interfere with each other. Additionally, one cortex screw may be inserted from the proximal phalanx in a proximal palmar or plantar direction into the MCIII or MTIII medial and lateral to the plate.

With comminuted proximal sesamoidean fractures, insertion of screws into the proximal sesamoid bones is not possible. Also, in cases where the distal sesamoidean ligaments are ruptured, inserting the lag screws into the proximal sesamoid bone does not produce a tension band across the palmar or plantar joint surface. In such cases, a double strand of 1.5-mm diameter cerclage wire is placed in figure-eight fashion across the palmar or plantar aspect of the joint. A 3.2-mm hole is drilled in a frontal plane parallel to the joint surface at about 4 to 6 cm proximal and distal to the joint surface across the MCIII or MTIII and the proximal phalanx, respectively.
The wire is guided through these holes and directed toward the palmar or plantar joint surface with the help of the large wire passer (Synthes Inc, Solothurn, Switzerland). The wires are passed around the suspensory apparatus in a figure-eight pattern such that the two wires can be twisted together into one unit. Wires are tightened with the joint maintained in slightly flexed position. One set of wire ends is tightened on the lateral side of the MCIII or MTIII and the other set on the medial side of the bone. Prior to final tightening, all the slack has to be taken out of the wire to ensure the development of an effective tension band function. The remainder of the procedure is identical to the one described earlier.

A 16-hole 5.5 LC-DCP may be used to treat a severely comminuted proximal phalangeal fracture when an arthrodesis of the MCP or MTP joint and the PIP joint is desired (Fig. 85-8).

**Dynamic Hip Screw Plate Technique**

An alternative technique involves application of a dynamic hip screw (DHS) plate 5,28 (Fig. 85-9). Plate application is identical to the dynamic condylar screw (DCS) plate application described in Chapter 81. The lateral aspect of the MCP or MTP joint is prepared for plate application. The palmarolateral or plantarolateral aspect of the distal condyle is removed with an osteotome or an oscillating saw. A 2.5-mm hole is drilled from the level of the MCP or MTP joint into the proximal phalanx after aligning the joint at the desired angle. A drill guide with the preset screw angle facilitates placement of the drill hole. Correctness of the drill hole is monitored by intraoperative radiographs or the use of a fluoroscope.

When the position is correct, the 2.5-mm guide pin is introduced into the predrilled hole and seated in the opposite cortex. The guide pin has an inadequate cutting edge and is incapable of self-cutting, so a 2.5-mm drill bit is used to create its hole through dense equine bone. The length of the screw to be inserted is determined using the measuring device, and with the triple reamer for the DHS plate set at the correct distance (5 mm shorter than the pin length as measured to be located in the bone), the shaft and the barrel hole are prepared.

Using the tap placed over the guide pin, the threads for the lag DHS screw are cut. Care is taken to engage the opposite cortex; otherwise adequate stability will not be achieved. The plate is placed over the screw shaft and aligned along the axis of the bone. The connecting screw is subsequently inserted and tightened, followed by the insertion of the 5.5-mm-diameter cortex bone screws into the MCIII or MTIII. Two additional transarticular cortex screws are placed from the proximal aspect of the proximal...
phalanx in a proximopalmar or proximoplantar direction into the MCIII or MTIII using lag technique. Additionally, cortex screws may be inserted in lag fashion into the proximal sesamoids if the injury allows application. Alternatively, a tension band wire as described earlier may be applied prior to plate application in cases where no natural tension band can be established along the palmar or plantar joint surface. The subcutaneous tissues and skin are closed using routine technique. Application of a cast for 3 to 4 weeks is indicated.

Other Techniques
An arthrodesis technique using a prototype of an intra-medullary pin plate (IMPP) has been compared in vitro with a dorsal DCP technique. The study revealed a significantly greater mean yield load, yield stiffness, and failure load (axial compression, torsional loading) of the IMPP compared with the DCP system. Mean cycles to failure for axial compression was significantly greater for the IMPP compared with the DCP system. The IMPP was superior to the DCP system in resisting the biomechanical forces most likely to cause failure of MCP joint arthrodesis. Therefore, the IMPP implant might represent an interesting alternative for MCP arthrodesis in horses with traumatic disruption of the suspensory apparatus in the future.

Description of the modified Cloward technique for MCP/MTP arthrodesis has been proposed, but it has not been pursued lately. This approach, however, does not represent an improvement over the techniques described here.

Carpal Arthrodesis
Indications
In the carpal region, two types of arthrodeses are performed: the pancarpal arthrodesis, where all the joints in the carpus are fused, and the subtotal or partial arthrodesis involving only one or two of the joints. Carpal arthrodeses are indicated for treatment of comminuted carpal fractures as well as luxations and subluxations of this region. In most animals, these operations should be viewed as salvage procedures, with the exception of animals with carpo-metacarpal luxations. Partial carpal arthrodeses are recommended in cases in which the distal row of carpal bones has comminuted fractures and accurate anatomic reconstruction is impossible or in luxations of the carpometacarpal and the middle carpal joints.

Surgical Techniques
Partial Carpal Arthrodesis
Depending on the injury, partial carpal arthrodesis involves either fixing the proximal row of carpal bones to the distal row and MCIII or fixing the distal row of carpal bones to the MCIII (Fig. 85-10). Additionally, partial carpal arthrodesis can be used for antebrachiocarpal luxations, where the proximal row of carpal bones is fastened to the distal radial epiphysis or metaphysis. For these arthrodesis techniques, a variety of plates may be used. Selection depends on availability of the plates and preference of the surgeon. The surgical incision is made in the region in which the plate

(From Auer JA, Taylor JR, Watkins JP, et al: Vet Comp Orthop Traumatol 1990;3:51.)
Figure 85-11. A, Dorsopalmar radiographic view of subluxation of the middle carpal joint in a 6-year-old brood mare. Note the avulsion fracture at the medial aspect of the carpometacarpal joint. The 2nd carpal bone is also partially luxated. B, Postoperative dorsopalmar radiographic view showing a broad six-hole 4.5 DCP applied to dorsomedial aspect and a narrow five-hole 4.5 DCP applied to the dorsal aspect of the carpal region to achieve a partial carpal arthrodesis.

Whenever possible, articular cartilage should be removed to allow fusion of the joint surfaces. Performance of osteostixis as well as a cancellous bone graft, tricalcium phosphate granules, or high molecular weight gel inserted into the joint are indicated to facilitate fusion. In comminuted carpal bone fractures, strategically placed interfragmentary screws inserted in lag fashion contribute considerably to stability of the joint. In most cases, it is prudent to maintain alignment by applying one or two bone plates across the joint involved. The same holds true for selected subluxations with signs of avulsion fractures and displacement of specific bones (Fig. 85-11).

In a mare with severely comminuted fractures, all the fragments of the distal row of carpal bones were removed, with subsequent fixation of the proximal row of carpal bones to the MCIII. After 3 months in a tube cast, the mare developed fusion in the arthrodesis site and served for several years as a successful brood mare.

Pancarpal Arthrodesis

Pancarpal arthrodesis using two long, broad DCPs or leg-lengthening plates is advocated for comminuted fractures involving both rows of carpal bones (Fig. 85-12) and for severe degenerative carpal joint disease in older horses that develop carpus valgus. The 5.5 LC-DCP, DHS, or DCS plates are excellent alternatives to these implants, because they are stronger. Simple cast application is not effective in these cases.

In severely comminuted fractures, the purpose of the plates is to buttress the unstable limb and maintain a straight axis. In these cases, the leg-lengthening plates may be superior to the routine LC-DCPs, because they do not contain holes in the middle portion. Occasionally a plate hole must be left open in severely comminuted fractures because the size of the underlying fragment may be inadequate to accept a screw. These plate holes are a site of decreased strength and can doom the repair to failure.

Plate luting is indicated in pancarpal arthrodeses (see Chapter 81). The plates might have to be inserted through two separate approaches, which, after application of the implants, are closed using routine techniques. Splints or casts may be necessary, depending on the injury that led to the partial or pancarpal arthrodeses.

SCAPULOHUMERAL JOINT ARTHRODESIS

Indications

Advanced osteoarthritis and persistent luxations and subluxations of the scapulohumeral (SH) joint in Shetland or Icelandic ponies may be treated by arthrodesis with the aim to render the animals free from painful lameness. This technique is not well suited for horses, because the quality of bone in this region is inadequate to withstand the tremendous mechanical forces that would be exerted on the implants.

Surgical Technique

A 10- or 11-hole, 4.5-mm narrow LC-DCP or DCP and 4.5-mm cortex screws are applied to the cranial surface of the scapula and cranial surface of the humerus after
osteotomy of the intermediate tubercle (Fig. 85-13). A broad 3.5 LC-DCP or a reinforced 3.5 DCP are alternative implants. They have the same cross-sectional area as the narrow 4.5 DCP, but more screws can be inserted through these other plates, which provides a biomechanically superior fixation. In most horses, one or two plate holes over the joint should be filled with transarticular screws inserted in lag fashion.

A report of four miniature horses suffering from SH osteoarthritis, some with concurrent shoulder luxation or subluxation, described SH arthrodesis as a successful technique, despite some complications.45 The animals developed a mechanical lameness but were able to ambulate well after surgery.

TARSAL ARTHRODESIS

Indications

The primary indication for tarsal arthrodesis is osteoarthritis (spavin) of the tarsometatarsal, distal, and possibly proximal intertarsal joints that is unresponsive to medical therapy.2,33-36 Occasionally, luxations of the tarsus, especially involving the tarsometatarsal and distal intertarsal joints, necessitate arthrodesis. Talocalcaneal arthrodesis has been described as a promising treatment for talocalcaneal osteoarthritis.37,38

Distal Intertarsal Arthrodesis

Chemical Arthrodesis

Some time ago, chemical arthrodesis through intra-articular injection of 100 mg of monoiiodoacetic acid (MIA) was introduced as a treatment for osteoarthritis of the tarsometatarsal and distal intertarsal joints.19,40 Pronounced synovitis occurs for 12 to 24 hours after injection and is managed with sedation and analgesia with detomidine. Patients are pretreated with phenylbutazone before injection. MIA is injected three times at 10-day intervals. Joints fuse within 6 months; some residual lameness can persist.

The severe inflammation induced by MIA causes destruction of the articular cartilage, which is followed by bone union. Because of the reaction caused by the drug, it is essential that only the joints to be fused are injected. Occasionally, communication exists between the distal and proximal intertarsal joint, and the communication permits the drug to enter the tarsocrural joint with fatal consequences. Therefore, a positive contrast arthrogram of the joint or joints to be treated before MIA injection is strongly advised to assess ectopic communications. For additional information on this technique, see Chapter 99.

Surgical Techniques

The animal is positioned in lateral recumbency, providing access to the dorsomedial aspect of the tarsus involved. If the procedure is performed in both hindlimbs at the same time, the horse is positioned in dorsal recumbency. After routine preparation of the surgical site for aseptic surgery, a 10- to 15-cm straight skin incision is made, centered over the tarsometatarsal joint. The saphenous vein, which crosses the surgical field diagonally, is isolated and retracted. Placement of a Penrose drain around the vein facilitates its manipulation during the surgical procedure. The cunean tendon is dissected and approximately 5 cm of its length within the surgical field is removed. During preparation and resection, the cunean bursa is inevitably opened and partially destroyed. The tarsometatarsal and distal intertarsal joints are identified with hypodermic needles. Several techniques merit discussion.36

DRILLING TECHNIQUE

A 3.2- or 4.0-mm drill bit is passed into the joint space in three directions from a single entry point on the medial aspect of the hock, creating a fan-like pattern of holes extending dorsolaterally, laterally, and plantarolaterally for 2 to 3 cm6 (Fig. 85-14). Frequent cleaning of the bit and use of a new bit for each horse is recommended to decrease the potential for bit breakage. The holes fill first with blood, then with fibrous tissue, and ultimately with bone, effectively bridging the joint in spot-weld fashion. This technique causes little pain and allows about 80% of the horses to return to soundness within 6 to 9 months.34,36,39,40

Drilling too deeply can penetrate the tarsal canal, resulting in unnecessary periosteal reaction or profuse hemorrhage from disruption of the perforating branch of the cranial tibial artery. Excessive drilling causes instability, severe pain, and prolonged recumbency and is associated with excessive periosteal new bone formation.41 Most of the horses in which excessive drilling has been performed never regain complete soundness.41

Local cartilage destruction of these joints also has been achieved with the help of surgical lasers.42 The results are similar to the drill hole technique. However, some experience is necessary because excessive cartilage destruction using the laser also leads to massive new bone formation and prolonged lameness.

Figure 85-13. Graphic illustration of a scapulohumeral arthrodesis using a bone plate applied to the cranial aspect of the bones.
FIXATION TECHNIQUES

One technique consists of application of a narrow DCP over the medial aspect of the tarsal region (Fig. 85-15). Fibrous covering of the dorsomedial aspects of the joints together with any exuberant exostoses are partially removed with an osteotome and mallet. This facilitates identification of the joint spaces involved, provides a greater plate–bone contact area, and allows less contouring of the plate. The proximal intertarsal joint space is identified through placement of two hypodermic needles or two 2-mm drill bits. Either a radiographic examination is conducted at that stage or the image intensifier is applied to verify correct location.

As an optional procedure, two drill holes 4.0 mm in diameter are prepared along each of the joints as previously described.44 These holes may be filled with a bone graft plug harvested from the proximal tibia or the tuber coxae. Placement of such a plug, hydroxyapatite granules, or biodegradable bone cement will enhance osseous union of the two articulations by means of spot welds.

The desired five-hole narrow 4.5-mm DCP is applied to the arthrodesis site. The thread hole for the most proximal plate screw is drilled with the 4.0-mm drill bit protected by the corresponding drill guide within the body of the central tarsal bone, parallel to the joint surfaces. In smaller horses, 4.5-mm screws may be used instead of 5.5-mm. In that case, a 3.2-mm thread hole will be prepared. (It is important to use 5.5-mm cortex screws whenever possible, because they resist cyclic loading better than 4.5-mm screws. Screws 4.5 mm in diameter often fail in an adult horse.)

After tapping the thread hole, a 30- to 40-mm long cortex screw is inserted through the most proximal plate hole and tightened. Care is taken to avoid impacting the selected screw upon the dead-end hole. The tension device is applied subsequently at the distal end of the plate, secured to MTIII, and tightened. One or two plate screws are subsequently inserted into the third metatarsal bone. After the tension device is removed, the remaining plate holes are filled with screws. If the distal intertarsal and tarsometatarsal joints are to be fused, one screw is inserted into the central tarsal bone and one into the third tarsal bone (Fig. 85-16).

After flushing the surgical site, the subcutaneous tissues and the skin are closed in routine fashion. The surgical site is covered by a bandage.

Postoperatively, the limb is kept under a bandage for 2 to 3 weeks. The skin sutures or staples are removed 10 days after the surgery. Lameness can persist for several months. Rehabilitation must be conducted gradually over several months.

An alternative technique involves implantation of perforated stainless steel cylinders filled with autogenous cancellous bone in the distal tarsal joints.43 This technique was applied in four horses. Graft cell survival was poor 2 weeks after surgery in one horse. In two horses at 10 months, there was partial arthrodesis of the joints with incorporation of the implants into the osseous union. The implants were filled with vascularized woven bone. These two horses were sound 9 months after surgery, but one horse fractured its third tarsal bone and was still positive to a hock flexion test 12 months after surgery.

A more involved technique that is occasionally used in tarsal luxations involves the application of a 12- to 14-hole...
5.5 LC-DCP or broad DCP to the plantarolateral aspect of the calcaneus and proximal MT region (Fig. 85-17). This technique allows extension of the plate farther proximally, resulting in a stronger arthrodesis. In selected cases, MTIV is removed before plate application. However, care must be taken to avoid damage to the greater metatarsal artery coursing between MTIII and MTIV. The surgical approach is more extensive than that for the technique described earlier, and the surgery itself is more demanding. Care must be taken to avoid penetration of the tarsocrural joint with a screw. Selected screws can be placed in lag fashion across the more distally located joints, facilitating interfragmentary fixation.

**Talocalcaneal Arthrodesis**

For talocalcaneal arthrodesis, the horse is placed under general anesthesia in lateral recumbency, with the affected limb positioned uppermost. Application of a tourniquet proximal to the tarsus is optional. A slightly curved incision is made over the distal half of the calcaneus, and the tissues are sharply divided down to the bone.

Needle markers are used to determine under fluoroscopic control the correct angulation of the future screws. Computer-assisted guidance greatly facilitates preparation of the drill holes (see Chapter 14). The drill bit is aimed toward the plantaromedial aspect of the medial trochlear ridge of the talus, avoiding penetration of the tarsocrural joint at the intertrochlear groove.

Two or three 5.5-mm cortex screws are inserted in lag fashion across the lateral facet, using routine technique

---

**Figure 85-16.** Dorsoplantar (A) and lateromedial (B) 4-week postoperative radiographic views of a tarsal arthrodesis using a four-hole narrow DCP in a 9-year-old Andalusian gelding. One 5.5-mm cortex screw is inserted into both the central and the third tarsal bones. Two identical screws are placed into the proximal MTIII. Note that the drill holes into the two distal joints are already filling in with new bone and becoming less obvious on these radiographs.

**Figure 85-17.** Oblique postoperative radiographic view of the tarsal region of a horse that suffered luxation of the proximal intertarsal joint. A 12-hole broad DCP was applied palmarolaterally to the calcaneus and proximal MT region. Some minor displacement is still present. (Courtesy J. P. Watkins, Texas A&M University.)
(Fig. 85-18). There is an adequate amount of solid bone present to achieve solid transarticular compression. By slightly altering the direction of the screws, an increased compressive effect can be achieved. To prevent weakening of the calcaneal bone, washers may be applied, which negate the need for countersinking.37 Alternatively, the screws may be inserted through a plate contoured to the calcaneal surface. Once the screws are in place and solidly tightened, the incision is closed using routine technique.37

A slightly different technique was presented in another paper, where two clinical cases were also treated with 5.5-mm cortex screws applied in lag fashion. In a pony, three parallel screws were inserted through a dorsomedial arthrotomy to the talus across the medial facet into the calcaneus; in a horse, identical screws were augmented with two additional screws similarly inserted as described in the first technique.38 Both techniques resulted in successful fusion.6,44 Talocalcaneal arthrodesis could develop into an effective treatment for local talocalcaneal osteoarthritis. Early results are encouraging.

COMPLICATIONS
Complications include postoperative infection, implant failure, laminitis in the opposite limb, long-term lameness, and development of angular limb deformities. Accidental insertion of bone screws into a joint space can provide a continuous source of pain and should be avoided. This can be done by meticulous surgical technique and careful intraoperative radiographic control.

Diagnosis and Management of Tendon and Ligament Disorders
Charlotte S. Davis
Roger K. W. Smith

TENDON BIOLOGY
Structure of Tendons and Ligaments: From Molecule to Organ

Tendons and ligaments are complex organs built up in a hierarchical arrangement of increasingly smaller subunits (Fig. 86-1). Tendon is highly hydrated, having a water content of around 70%, and the remaining 30% (the dry weight) is composed predominantly of type I collagen. Collagen is synthesized as procollagen molecules consisting of an α-helical chain and amino-terminal and carboxy-terminal extensions that are cleaved by procollagenases immediately before three α-chains are combined to give a single collagen fibril. This process appears to take place postnataally outside the cell, but recent evidence has suggested that the original structural template for tendon formation is laid down by cells in the embryo that secrete acellular fibrils into the extracellular space. From these data, it was proposed that COMP molecules bring together the spatial organization of the collagen fibrils and their crosslinking. The determination of collagen fibril size, organization, and crosslinking is provided by an array of noncollagenous proteins, many of which are yet to be characterized fully. The next most abundant protein in young tendon is cartilage oligomeric matrix protein (COMP), which is believed to be involved in the organization of the collagen fibril framework during formation and growth. In support of this proposed action, recent experimental data showed that COMP accelerated collagen fibril formation in vitro. From these data, it was proposed that COMP molecules bring together...

TENDON BIOLOGY

Structure of Tendons and Ligaments: From Molecule to Organ

Tendons and ligaments are complex organs built up in a hierarchical arrangement of increasingly smaller subunits (Fig. 86-1). Tendon is highly hydrated, having a water content of around 70%, and the remaining 30% (the dry weight) is composed predominantly of type I collagen. Collagen is synthesized as procollagen molecules consisting of an α-helical chain and amino-terminal and carboxy-terminal extensions that are cleaved by procollagenases immediately before three α-chains are combined to give a single collagen fibril. This process appears to take place postnatally outside the cell, but recent evidence has suggested that the original structural template for tendon formation is laid down by cells in the embryo that secrete procollagen molecules. Accelerated collagen fibril formation in vitro. From these data, it was proposed that COMP molecules bring together the function of the tendon depends on the spatial organization of the collagen fibrils and their crosslinking. The determination of collagen fibril size, organization, and crosslinking is provided by an array of noncollagenous proteins, many of which are yet to be characterized fully. The next most abundant protein in young tendon is cartilage oligomeric matrix protein (COMP), which is believed to be involved in the organization of the collagen fibril framework during formation and growth. In support of this proposed action, recent experimental data showed that COMP accelerated collagen fibril formation in vitro. From these data, it was proposed that COMP molecules bring together...
five separate collagen molecules in the “quarter-stagger” that is characteristic of collagen fibrils. Once these collagen molecules have formed a fibril, COMP no longer functions in binding and is displaced from the collagen fibril. In keeping with this role, levels of COMP in equine digital flexor tendons increase dramatically during growth, peak at around 2 years of age in the metacarpal region of the equine digital flexor tendons, and then decline once growth ceases and the animal ages.2 The importance and relevance of this protein during growth is suggested by a correlation between tendon ultimate tensile strength and the level of COMP at skeletal maturity.4

Tendons also contain a wide variety of other non-collagenous proteins, many of which have yet to be characterized. The composition varies along the length of the tendon, reflecting the biomechanical environment. Hence, the small proteoglycans (decorin, fibromodulin, lumican, and mimecan) predominate in the tensional regions, whereas the large proteoglycans (aggrecan and versican) are mainly, but not exclusively, located in the regions of the tendon that are subjected to compression as the tendon changes direction over a bony prominence (e.g., the deep digital flexor tendon at the level of the metacarpophalangeal joint).5,6

Bundles of collagen fibrils are grouped together into fibers that are separated by cytoplasmic extensions of the cellular components of tendon, known as tenocytes7 (Fig. 86-2). Little is known about these cells, although several different types are identified on light microscopy on the basis of their nuclear morphology.4,9 These different nuclear shapes may represent stages of activation or differently differentiated cells. Type I cells, which have thin, spindle-shaped nuclei characteristic of adult tendon, are most likely to be relatively inactive forms of the type II cells, whose nuclei are more oval and that are abundant in young, growing tendon. In adult digital flexor tendon, where the tendon changes direction over the palmar/plantar aspect of the metacarpophalangeal/metatarsophalangeal (MCP/MTP) joint, external compression results in a matrix that is more like that of fibrocartilage. Reflected in this matrix, type III cells have round nuclei characteristic of chondrocytes. Other cell types are found within the endotenon (see later) and are associated with aging changes (e.g., chondroid metaplasia). On a large scale, collagen fibers are grouped together in increasingly larger subunits divided by looser connective tissue known as the endotenon. It is these subunits, known as fascicles, that are visible to the naked eye on a cut section of tendon (Fig. 86-3). In relaxed tendon, the fascicles have a waveform known as crimp, which is best seen under polarized light. The endotenon carries blood vessels and nerves and is the location of a different type of cell, one that has a more rounded shape; these cells are believed to be the source of mesenchymal stem cells within the tendon. This compartment of the tendon contains higher levels of certain growth factors, such as transforming growth factor (TGF)-β, than within the fascicles.10

The endotenon is continuous with the layer of connective tissue surrounding the outside of the tendon, known as the epitenon. Outside this layer, around tendons that are not contained within a tendon sheath, is a thicker layer known as the paratenon, which is able to stretch considerably and is therefore rarely ruptured when a tendon suffers a strain injury. This layer is believed to play particularly important roles both in reducing frictional forces between the tendon and the surrounding soft tissues and as a supplier of new blood vessels and cellular elements for repair. It is hypothesized that the lack of this layer intrathecally and the synovial fluid environment results in slower healing of these regions.

Where tendon changes direction over a joint, the tendon usually is enclosed within a tendon sheath (Fig. 86-4). This structure provides a synovial environment for the smooth
gliding of tendon over a bony prominence. Associated with this sheath, there is usually a smooth fibrocartilaginous pad covering the bony prominences, best exemplified by the scuta of the distal limb—the proximal scutum or intersesamoidean ligament at the level of the MCP/MTP joint, the middle scutum attached to the middle phalanx, and the distal scutum attached to the distal sesamoid (navicular) bone. The tendon sheath, like a joint, consists of an outer fibrous wall and an inner synovial membrane, which also surrounds the tendons within the tendon sheath. Dividing the sheath into complete or incomplete compartments are a number of mesotenons that are composed of two layers of synovium and frequently, but not always, carry the blood supply to the tendon.

**Blood Supply**

The blood supply to the tendon comes from its muscular origin and osseous insertion and variably from accessory ligaments, the paratenon, and mesotenon attachments. However, work on equine digital flexor tendons showed that stripping the paratenon failed to cause any ischemic damage to the tendon,11,12 indicating the importance of the intratendinous supply for this tendon. Based on the microvascular anatomy determined by microradiographs,13 this intratendinous supply is most abundant around the periphery of the tendon, which has led to the hypothesis that the central region of the tendon is relatively hypoxic, and that this is one of the reasons for the common manifestation of tendon disease as a central core lesion. However, there is little supporting evidence for this hypothesis and, in fact, the superficial digital flexor tendon has a blood supply, as determined by xenon clearance, similar to that of resting skeletal muscle and is capable of increasing flow during exercise and after injury.14

**Functional Characteristics of Tendon and Ligament**

Tendon and ligaments have a variety of functions: they transmit forces to move the equine skeleton, or they provide support of the distal limb in the case of the digital flexor tendons, or, as ligaments, they maintain joint integrity. Their structure is optimized to play these mechanical roles.

Tendons and ligaments have viscoelastic properties, which means that their mechanical properties vary as they are stretched. A typical force–elongation curve for tendon is shown in Figure 86-5. Initially, the tendon stretches under relatively little load, which is associated with the elimination of crimp in the fascicles. Thereafter, the curve is almost linear. It is from this area of the curve that the structural property of stiffness is determined (load divided by deformation). As the load increases further, there is a change in the gradient such that the tendon becomes less stiff. This is known as the *yield point*, and it is thought to arise from covalent crosslink rupture and slippage of collagen fibrils. If the tendon is stretched past this point, irreversible damage occurs. If loading is continued past this point, the tendon ruptures, which for the equine superficial digital flexor tendons (SDFT) is approximately 12 kilo-newtons (kN) or 1.2 tons (ultimate tensile strength).15,16

If the cross-sectional area and length of the tendon is known, then the stress (force per unit area) can be plotted against strain (change in length over original length), from which the material properties of ultimate tensile stress (N/mm²) and Young’s modulus of elasticity (E [MPa]) can be calculated. The approximate ultimate tensile stress of 100 MPa for the equine SDFT is similar to previously documented figures in other species (20 to 144 MPa).17,18
In vitro, equine flexor tendons can extend 10% to 12% of their length before they rupture (ultimate tensile strain), and values of up to 20% have been reported. However, the ultimate tensile strain reflects only the final strain before rupture and includes the yield portion of the stress–strain curve that represents irreversible damage to the tendon tissue. The normal strains in the digital flexor tendons, recorded in vivo, are in the region of 3% to 8% at the walk, 7% to 10% at the trot, and 12% to 16% at the gallop. Such strains, far greater than usually expected in tendons from most other species, may reflect the importance of the digital flexor tendon as an elastic energy store, where maximal deformation stores the most energy but also makes them operate close to their functional limit.

In addition to these basic functional characteristics, tendon has other mechanical properties of potentially important biologic relevance. There is a difference between the stress–strain relationship when the tendon is loaded and the relationship when it is unloaded, which is known as hysteresis (see Fig. 86-5). The area between these two curves represents the energy lost during the loading cycle. This is usually about 5% in equine tendons. Much of this energy is lost as heat and is responsible for the rise in temperature in the tendon core when the horse exercises. These temperatures can rise to as high as 44°C, which is potentially damaging to both tendon matrix and tenocytes. However, tenocytes recovered from the center of equine SDFT remain viable when subjected to rises in temperature of this magnitude, whereas those recovered from the periphery of the tendon do not. This property is also present in fetal tenocytes, which suggests that the tendon has an inherent genetic adaptation to this physical process.

The loading rate has only a minimal effect on tendon biomechanics: a rapid loading rate results in a stiffer tendon, whereas repeated loading, in contrast, results in a less stiff tendon, a process known as conditioning (see Fig. 86-5). This effect appears to occur in vivo and the change is recoverable but significant resting time is necessary.

The Relationship of Structure to Function

It would appear that all tendons are formed in utero in a similar fashion and with a similar composition, analogous to the “blank joint” concept for articular cartilage. However, as soon as the animal is born and stands, tendons and ligaments receive very different mechanical loading. It is believed that different mechanical environments drive growth and differentiation of tendons so that at skeletal maturity, different tendons have different compositional and structural properties that relate to their function. Thus, mature tendons are not all composed of the same material and hence do not all have the same functional characteristics. Furthermore, different loading patterns induce anisotropy within certain tendons. Thus, where the digital flexor tendons change direction across the palmar aspect of the MCP/MTP joint and are subjected to external compression, they develop a cartilage-like matrix.

The horse’s distal limb is designed like a spring to store energy from weightbearing for the subsequent stride. The horse essentially bounces up and down on its forelimbs, whereas its hindlimbs provide propulsive force. This system is optimized by having a hyperextended MCP joint and by the energy being stored in the palmar soft tissue structures, principally the SDFT and suspensory ligaments (Fig. 86-6). The superficial digital flexor muscle contains a high proportion of fibrous tissue, and recent data have indicated that its maximal contraction shortens the muscular unit by only 2 mm. Hence, the muscle acts not to flex the MCP joint but rather to fix the origin of the SDFT and dampen high-frequency damaging oscillations. Although the muscle within the suspensory ligament is considered vestigial, it may also have a similar role in dampening the damaging oscillation during high-speed exercise.

Consequently, these two structures have very similar matrix compositions and configurations: both have high COMP levels and a combination of small and large collagen fibrils. In contrast, the common digital extensor tendon (CDET), a low-load tendon, and the deep digital flexor
tendon (DDFT), which also has a different role, have lower levels of COMP and predominantly large collagen fibrils. These compositional differences are reflected in their mechanical properties. Tendons can be divided into weight-bearing tendons that function like springs (and are less stiff, or more elastic) and those that position the skeleton (which requires greater stiffness). Thus, the CDET is almost twice as stiff a material as the SDFT.

**Etiopathogenesis of Tendon Injury**

Tendons and ligaments can be injured in one of two ways: by overstrain or percutaneously. Overstrain injuries are believed to occur by one of two mechanisms. They can result from a sudden overloading of the structure, which overwhelms its resistive strength. This type of injury is probably the mechanism for most ligament and some DDFT injuries in the horse. However, for the most common strain-induced injuries in the horse, involving the palmar soft tissue structures of the metacarpal region, the clinical injury is believed to be preceded by a phase of molecular degeneration ("molecular inflammation"), which induces neither a clinically evident inflammatory reaction nor any reparative response, but instead progressively weakens the tendon. The evidence for this degeneration is based on four observations:

- "Asymptomatic" lesions are present both grossly and microscopically in postmortem studies of normal horses. However, analysis of these lesions suggests that they are the result of healing of low-grade clinical injuries rather than true degeneration.

  Most clinical strain-induced tendinopathies are bilateral, but one limb is more severely affected than the other (Fig. 86-7). Careful ultrasonographic examination often reveals changes in the contralateral limb. Furthermore, in seemingly unilateral cases, blood flow studies have demonstrated increases in the "normal" contralateral tendon, which would suggest that it is not totally unaffected.

  Epidemiologic studies in both horses and humans have shown strong associations between injury rates and age.

  A number of experimental exercise studies and postmortem analyses of normal tendons have indicated that increasing age and amounts of exercise induce tendon matrix degeneration rather than adaptation in the adult horse.

**Response of Tendons to Aging and Exercise**

When evaluating the gross mechanical properties of the SDFT in a large group of normal horses, there is a reduction in tendon strength with age, but this is statistically insignificant because of high variance. Thus, in a population of normal horses, there is more than a twofold variation in ultimate tensile strength of the SDFT. This high variance arises from inaccuracies in measuring ultimate tensile strength in vitro and the true variation in tendon strength, which is influenced by genetic components, but probably most importantly by environmental factors of aging and exercise.
The collagen crimp angle and length showed a regional reduction in the central core with exercise and age, both acting synergistically.\textsuperscript{33,34} This results in the central fibers being straightened first under loading, and hence they are the most likely to rupture first, giving rise to a possible mechanism for the generation of the "core lesion" frequently seen clinically (Fig. 86-8).

Within the matrix, regional differences in collagen fibril diameter are seen in long-term exercised older horses but not in short-term exercised, or younger, horses.\textsuperscript{35} The higher proportion of small fibrils in the central region of long-term exercised horses does not appear to be associated with increased collagen content, and the collagen-related fluorescence (a measure of collagen age) is unaltered, suggesting that this change results from disassembly of the larger-diameter fibrils.

Collagen content varies little with age and exercise, but the noncollagenous component of tendon is much more labile, with changes evident in longer-term exercised and older horses. Thus, in the center of the tendon where clinical injury is seen, there is an accelerated loss of glycosaminoglycans (GAG) and COMP. This is in contrast to the central discolored regions seen as an occasional coincidental finding at postmortem, which contain higher hydration and discolored regions seen as an occasional coincidental response.\textsuperscript{37} Interestingly, this age effect is not apparent in tendons do demonstrate a small, but significant, reduced response.\textsuperscript{37} The mechanism of degeneration of the tendon is currently unknown, but there are several possibilities. The close association between age and exercise suggests that the number of loading cycles is important, and it is logical to presume that the highest loading rates are likely to be the most damaging, so the amount of time spent at the fastest gaits (canter and gallop) are likely to contribute to degeneration. The actual mechanisms can be either physical or indirect physical effect of weightbearing is via the energy lost through hysteresis.\textsuperscript{38} This results in a temperature rise at the center of the tendon, which has been recorded to be as high as 44° C at the gallop (Fig. 86-9). Although tenocytes in the SDFT have been shown to be resistant to these temperature rises,\textsuperscript{29} this temperature could still be damaging to matrix proteins. Cyclical loading of tendon explants in vitro

**Mechanisms for Tendon Degeneration**

Cumulative tendon microdamage arises from the induction of tendon matrix damage and the failure of the resident cell population to repair this damage. The mechanism for the failure of tenocytes to repair or adapt to exercise-induced microdamage in the adult is unclear but possibly involves both an absence of appropriate growth factor stimulus and a degree of cellular senescence. Investigations into the synthetic response by equine tenocytes to mechanical load (biaxial stretch) and growth factors (e.g., TGF-\(\beta\)) in vitro have demonstrated that tenocytes recovered from aged flexor tendons do demonstrate a small, but significant, reduced response.\textsuperscript{37} Interestingly, this age effect is not apparent in tenocytes recovered from digital extensor tendons, which appear to continue to remodel and adapt during maturity.

The mechanism of degeneration of the tendon is currently unknown, but there are several possibilities. The close association between age and exercise suggests that the number of loading cycles is important, and it is logical to presume that the highest loading rates are likely to be the most damaging, so the amount of time spent at the fastest gaits (canter and gallop) are likely to contribute to degeneration. The actual mechanisms can be either physical or metabolic. The physical energy imparted to the tendon under weight-bearing load can produce direct damage to the matrix by disrupting crosslinks or actual matrix proteins. An indirect physical effect of weightbearing is via the energy lost through hysteresis.\textsuperscript{38} This results in a temperature rise at the center of the tendon, which has been recorded to be as high as 44° C at the gallop (Fig. 86-9). Although tenocytes in the SDFT have been shown to be resistant to these temperature rises,\textsuperscript{29} this temperature could still be damaging to matrix proteins. Cyclical loading of tendon explants in vitro.
induces the upregulation of both synthesis and activity of proteolytic enzymes, and this can induce a reduction in strength. Furthermore, cleaved matrix proteins, generated either from direct physical forces or from enzymatic cleavage, can also provoke further matrix degradation, giving rise to an exercise-induced cycle of matrix degeneration. Further work is necessary to elucidate the mechanisms of soft tissue degeneration so that preventative strategies can be developed.

Mechanisms of Clinical Injury

STRAIN-INDUCED INJURY

Degeneration is usually the first phase of tendinopathy. Any change in the structural properties of the tendon does not have to be great, as the tendon is already operating close to its tolerance limit. Clinical injury occurs when the highest stresses encountered by the tendon overwhelm its structural integrity, resulting in irreversible damage. At heel strike, the loads rise most quickly in the soft tissue structures that support primarily the metacarpophalangeal joint: the SDFT and the suspensory ligament (SL) (Fig. 86-10). The load in the DDFT rises later during stance, which may help to explain why the SDFT and the SL are the most prone to injury.

Once the peak load on the tendon overcomes its structural strength, there is physical disruption to the tendon matrix. The clinical injury varies in degree from fibrillar slippage, with breakage of crosslinking elements, to fibrillar rupture and, in some cases, complete separation of tendon tissue. Once this occurs, the damage created induces a repair process not dissimilar to that found in other soft tissues, such as skin, characterized by inflammation followed by fibroplasia (scar tissue formation).

This process allows the incorporation of risk factors that have been identified for inducing tendinitis. These risk factors act to increase the peak loads on the SDFT, thereby increasing the risk of structural disruption. One of the most important factors is the speed of the horse. The faster the horse is going, the greater the risk of developing tendinitis.

Thus, a hard track surface is associated with tendinitis, since it increases the speed of the horse and also increases the peak impact loading. Slower surfaces (including soft track surfaces) tend to be protective. Other factors, such as the weight the horse is carrying, fatigue, and the shoeing, can all influence peak tendon loads in this way. Heel elevation has been shown to decrease the load on the DDFT and increase the degree of extension in the MCP joint, with toe elevation having the opposite effect. It may be thought, therefore, that low heels would be protective of tendinitis. However, epidemiologic studies have shown an association between low heel and long toe conformation and orthopedic injury, of which the most common were tendon and ligament injuries.

TENDON TEARS

The mechanism for the generation of tendon or ligament tears within synovial cavities is much less clear. The most common site is the DDFT (mainly in the forelimb) and the manica flexoria (predominantly in the hindlimb) in the proximal digital sheath (Fig. 86-11). For the former, higher pressures within the compressed portion of the DDFT as it passes over the palmar aspect of the MCP joint may cause "bursting" of the lateral (or, less commonly, of the medial) borders of the tendon. For manica tears, it is possible that the manica gets caught as it passes into the fetlock canal, and, as some of these tears have been seen after a prolonged period of tenosynovitis, this may be exacerbated by synovial hypertrophy within the sheath (making this passage even more restricted) or, less commonly, by the presence of adhesions.

PERCUTANEOUS TENDON INJURY

Percutaneous tendon injuries arise most frequently from trauma to the distal limb because of the minimal soft tissue cover. These injuries are usually associated with considerable contusion. Traumatic injuries involving over-reaches, wires, jumping injuries, and kicking injuries are the most frequent causes. Tendon laceration usually requires the tendon to be taut, so tendons are most frequently partially or fully severed when under weight-bearing load. The exception to this is the lacerations caused when limbs are caught (e.g., in wire), when repeated attempts to free the limb can saw through any associated tendon or ligament.

The most serious consequences follow trauma to the palmar aspect of the metacarpus or pastern. Up to 50% of the tendon can be lacerated and still provide full tendon function at the walk. In contrast, extensor tendon lacerations on the dorsal aspect of the distal limb, although common (especially in hindlimbs caught in wire), rarely have long-term functional consequences.

Figure 86-10. The force of individual tendons and ligaments of the equine distal limb during stance. Note the rapid rise in loading in the superficial digital flexor tendon and suspensory ligament (including what is thought to be damaging high-frequency "transients" at foot placement), whereas loading rises more slowly in the deep digital flexor tendon. This may help explain why injuries are much more common in the superficial digital flexor tendon and suspensory ligament than in the deep digital flexor tendon. (Courtesy Dr. Alan Wilson.)

Figure 86-11. The manica flexoria (between arrows).
Pathophysiology of Tendon Repair

Once the tendon suffers clinical injury with disruption of the tendon matrix, there is intratendinous hemorrhage initially, usually followed rapidly by an inflammatory reaction (Fig. 86-12). This inflammatory reaction results in an increase in blood flow, the development of edema, the infiltration of neutrophils, macrophages, and monocytes, and the release of proteolytic enzymes. Although this is the earliest stage of repair, designed to remove damaged tendon tissue, the response is thought to be excessive, causing further damage to the tendon. The inflammatory phase is usually short-lived, and it overlaps the reparative phase, which begins within a few days and lasts several months. This phase is associated with a pronounced angiogenic response and fibroblastic cellular infiltration (extrinsic repair). It is believed that intrinsic repair mechanisms (i.e., from the tendon itself) are limited. The result is the synthesis of scar tissue that has a composition different from that of tendon, with a higher ratio of collagen types III: I (about 50% compared with 10% for normal tendon), a higher hydration, and higher levels of GAGs (see Fig. 86-12).

The reparative phase of tendon healing merges with the remodeling phase, during which there is a gradual but incomplete transformation to a higher proportion of type I collagen as the scar tissue matures (see Fig. 86-12). The new collagen fibrils become thicker and crosslinked. Although mature scar tissue tends to be less stiff as a material than tendon, because large amounts are formed, the scarred tendon often results in a stiffer tendon than the original. As a result, the healed tendon becomes strong but is functionally inferior to normal tendon and is thus predisposed to reinjury, often at sites adjacent to the original injury, which potentially reduces performance.

This process is less efficient when injuries occur to an intrathecal tendon, which is thought to be the consequence of the absence of a paratenon and reduced extrinsic repair. In addition, any surface defect within a tendon sheath will be bathed in synovial fluid, which will slow or even halt repair.

DIAGNOSIS

Clinical Evaluation

Diagnosis of strain-induced tendon injury is usually based on history (frequently a preceding period of exercise) and the development of the signs of inflammation (pain, heat, swelling, and lameness) over the affected structure. Lameness, which is often severe in the early stages, is not always evident when a patient is presented to a clinician, and it tends to be related to the degree of inflammation rather than to the degree of damage. Similarly, once the inflammatory phase has passed (within 1 or 2 weeks), lameness usually resolves rapidly.

The posture and function of the limb may be altered depending on the structure damaged and on the severity of the injury. In the case of severe superficial digital flexor tendinitis, resting MCP joint angle may be normal because of the action of the other supporters of this joint (SL and DDFT). However, when loading on the limb increases (e.g., when the contralateral limb is raised off the ground), the affected limb shows greater than normal overextension of the MCP joint (Fig. 86-13). Severe damage to the SL has a greater effect on MCP joint extension. Complete disruption of the peroneus tertius produces a characteristic mechanical lameness because of disruption of the reciprocal apparatus. This allows tarsal extension when the stifle is flexed. Similarly, complete rupture of the extensor carpi radialis tendon results in hyperflexion of the carpus during limb protraction.

For subtle cases, careful palpation of the tendons and ligaments in the limb should be made with the limb both weightbearing and raised. Careful attention should be given to pain response, subtle enlargement, and consistency of the structure (soft after recent injury; firm after healing). The horse must be relaxed so that muscle activity does not tense the tendons and make them appear artificially firm. Careful visual assessment of bowing of the palmar contour of the tendon and ligament disorders.

Figure 86-13. Demonstration of significant damage to the superficial digital flexor tendon (and/or suspensory ligament). Increasing the load on the affected limb by lifting the contralateral limb causes an abnormal increase in the metacarpophalangeal joint extension.
metacarpal region can help to identify subtle superficial digital flexor tendinitis. This assessment also should include the contralateral limb, since many strain-induced injuries are bilateral but with one limb more severely affected than the other.

Percutaneous tendon injuries are usually associated with moderate to severe lameness and may or may not have a concurrent wound. If a wound is present, it should be initially cleaned and then explored digitally with sterile gloves to ascertain which structures are damaged. Small wounds may hinder full evaluation, because the site of the tendon laceration, sustained under full weight-bearing load, is unlikely to be visible in the wound when the horse is severely lame. In such cases, concurrent ultrasonographic examination is very helpful. Penetration injuries or partial severance of a tendon does not alter the function of the tendon, so, other than lameness, there are few alterations of limb conformation. Complete transection, however, is associated with significant alterations in limb conformation under loading (see later). If the laceration is complete, the proximal part of a lacerated tendon often recoils as a result of the action of the associated muscle. It is necessary to assess whether any synovial structures have been penetrated, since this is a common complication of trauma to the distal limbs.

Ultrasonography

For strain-induced tendinopathies, clinical examination, however, may not detect the most subtle injuries, and it provides a poor objective assessment of severity. Since prognosis is most dependent on the severity of the initial injury, it is prudent to evaluate the damaged area ultrasonographically, and this is best carried out approximately 1 week after the onset of the injury, since many lesions may expand during the initial few days. Modern ultrasound machines with a 7.5- to 10-MHz linear transducer produce excellent-quality images of the flexor tendons and SL. Although the metacarpal region can be evaluated ultrasonographically without clipping the hair, it is best to prepare the limb by clipping and washing (with a surgical scrub and alcohol) to obtain the best-quality images. The horse should stand square, and both transverse and longitudinal images should be obtained in a methodical fashion throughout the length of the region containing the injured tendon. For the metacarpal region, the area is divided up into seven zones, each with characteristic anatomy (Fig. 86-14). Alternatively, the distance between the transducer and the accessory carpal bone can be recorded. The palmar soft tissue structures of the metacarpus can be evaluated satisfactorily from the palmar aspect of the limb, except for the SL branches, which should be evaluated from the medial and lateral aspects of the limb, respectively. Both limbs should always be examined, since many cases of strain-induced tendon injury have bilateral components but with one limb more severely affected than the other.

Acute tendon pathology is manifest ultrasonographically by enlargement, hypoechoogenicity (focal or generalized), reduced striated pattern in the longitudinal images, and changes in shape, margin, or position (Fig. 86-15). Chronic tendinopathy is associated with variable enlargement and

In Robinson NE, editor: Current Therapy in Equine Medicine, Philadelphia, 1997, WB Saunders.)
echogenicity (often heterogeneous), and an irregular striated pattern is indicative of fibrosis (see Fig. 86-15).

Ultrasonography is particularly useful for the assessment of tendon lacerations, which are associated with small wounds that limit digital exploration. However, ultrasonographic assessment may be impeded because of air artifacts and skin contusions.

**Molecular Markers**

Molecular markers have the potential to contribute four useful parameters to the evaluation of equine tendon disease. First, they may be used to provide a diagnosis when other diagnostic tests are negative (rarely needed for first-time injuries of the SDFT, but may be useful for detecting reinjury). In this respect, they also may be useful for screening...
as part of a preventative strategy: early detection may enable preventative measures (e.g., altered training) to be introduced to minimize the risk of provoking a career-ending injury. Second, they may allow a more objective assessment of the severity of the pathology and therefore help to determine prognosis. Third, they may give information about the stage of the disease process, optimizing rehabilitation protocols. Finally, they may assist in the choice of treatment and provide an objective assessment of its efficacy.

To date, the diagnosis and assessment of stage, severity, and prognosis of equine tendinitis have been correlated to semiquantitative ultrasonographic changes, but this procedure is time consuming and has a relatively low sensitivity. In contrast, molecular markers have the potential to reflect specific processes, anabolic or catabolic, within the tissue of interest. Initial investigations assessed markers of both collagen I synthesis (carboxy-terminal propeptide of type I collagen [PICP]) and degradation (crosslinked carboxy-terminal telopeptide of type I collagen [ICTP]) after tendon injury. Tendinitis resulted in a significant rise in PICP concentrations, whereas ICTP concentrations were not different from those in the control group. These results indicated that serum concentrations of PICP are able to reflect changes in type I collagen formation in healing connective tissue in one area of the body. The results also suggest that PICP is not an entirely bone-specific marker if repair in tissues other than bone can contribute to concentrations in serum.

Another candidate, COMP, which is abundant in young tendon, also has been assessed. Synovial fluid levels were more than 10-fold higher than serum levels, and they were significantly raised only when tendon damage or sepsis was present within the tendon sheath. However, serum COMP levels were not significantly elevated with tendon disease, which is related to high natural levels of COMP in blood. Longitudinal studies with this marker have shown variable results, but rather than reflecting specific tendon pathology, serum COMP levels might be more useful for detecting joint disease or for determining whether training levels are too excessive and are damaging multiple soft tissues.

**Clinical Characteristics of Specific Strain-Induced Injuries**

For the SDFT, the clinical injury may be focal or generalized, one of the more common manifestations being a centrally located region of injury (the so-called core lesion seen ultrasonographically). Usually, the most severe level is located just below the mid-metacarpal region, but it can extend throughout most of the length of the metacarpal extrasynovial tendon and give rise to swelling on the palmar aspect of the metacarpal region (the “bowed” limb). Regions of the SDFT enclosed within a tendon sheath (carpal sheath proximally, digital sheath distally) are much less often affected, although this can be more common when the metacarpal region was previously injured.

Desmitis of the accessory ligament of the DDFT may occur as an isolated injury or in conjunction with superficial digital flexor tendinitis. Although ponies rarely suffer strain-induced tendinopathies, they do have a relatively high incidence of desmitis of the accessory ligament of the DDFT. Lameness is often mild, or even absent, in this injury. Swelling is restricted to the proximal half of the palmar metacarpus, immediately dorsal to the SDFT and surrounding the DDFT.
The SL can fail at any site along its length. Injury to its proximal region at its attachment onto the palmar/plantar aspect of the third metacarpus/metatarsus is often restricted to this area, whereas injuries to the branches usually occur separate from proximal suspensory desmitis and may extend into the body of the ligament. Some branch injuries may also “tear” into the MCP/MTP joint and result in persistent joint effusion and lameness (Fig. 86-16). Furthermore, the synovial fluid environment dramatically slows down healing processes (see earlier).

In contrast to the SDFT and the SL, the DDFT is most frequently injured within the digital sheath. It is not known whether these injuries have a preceding phase of tendon degeneration, but many are potentially the result of single excessive loading cycles. Two manifestations are seen clinically. The first arises within the substance of the tendon (although it may extend to the borders of the tendon) and is similar to other clinical manifestations of tendinitis. The second arises at the medial or lateral borders of the tendon, usually in the region of the MCP joint. Both lesions are invariably associated with a distended digital sheath, but the latter can be difficult to identify ultrasonographically if the tear does not extend into the body of the tendon (Fig. 86-17).

Other tendons can suffer from strain-induced injury, although much less commonly than that affecting the palmar soft tissue structures of the metacarpus. Ligament injuries tend to occur when the joint they span is loaded inappropriately, resulting in a degree of subluxation or even complete luxation.

Figure 86-16. A, A hypoechoic defect (arrow) in the lateral suspensory ligament branch, which communicates with the metacarpophalangeal joint, causing joint distention, persistent lameness, and slow healing. B, This communication was confirmed by arthroscopy.

Figure 86-17. Deep digital flexor tendon injury. A, Mid-substance strain injury. B, Surface tear. The surface tear can be easily missed with ultrasonography and requires tenoscopy for confirmation and débridement.
Clinical Characteristics of Specific Tendon Lacerations

Complete transection of specific palmar metacarpal tendons and ligaments produces characteristic alterations in limb conformation, which may indicate the tendon or ligament that has been lacerated (Fig. 86-18). With SDFT laceration, the MCP/MTP joint is hyperextended (dropped) relative to the normal limb when the limb is loaded, but in the standing horse can appear symmetrical to the joint in the contralateral limb. If the SDFT and DDFT are lacerated concurrently, in addition to the signs described for SDFT laceration, the toe will be raised from the ground. If the SL is completely transected in addition to the SDFT and the DDFT, there is complete loss of support of the MCP/MTP joint, which is hyperextended to the extent that the MCP/MTP joint contacts the ground during the stance phase. Complete loss of MTP/MCP joint support often causes the horse to be severely distressed.

Extensor tendon lacerations frequently involve the metacarpal and metatarsal regions, although lacerations proximal to the dorsal aspect of the carpus involving the extensor carpi radialis or common digital extensor tendons are not uncommon. Lacerations proximal to the tarsus may involve the cranialis tibialis, the long digital extensor tendon, or the peroneus tertius tendon. Lacerations of the extensor tendons generally do not result in significant gait abnormalities or lameness, although they may cause the horse to stumble onto the dorsal aspect of the MTP/MCP joint region at a walk and to be unable to protract the limb completely.

TREATMENT OF TENDON AND LIGAMENT INJURIES

Strain-Induced Tendinopathy (Tendinitis)

In 1964, Asheim described the common treatment of tendon and ligament injuries as "phlebotomy, local cooling, plaster bandaging and rest." Over the last 4 decades, many treatments have been proposed for the management of tendon injury, although few, if any, have convincing supporting evidence of efficacy, and some can even be considered deleterious or detrimental to healing. However, the basic principles described by Asheim of cooling, support, and rest remain integral parts of the management protocol. Acute tendon and ligament injuries are medical emergencies requiring prompt and appropriate treatment to reduce inflammation rapidly, since persistent inflammation may be responsible for further damage to the tendon.

Nonsurgical Therapies

PHYSICAL THERAPIES

Cold therapy

In the acute inflammatory phase of tendon injury, cold therapy is an important aspect of treatment because it is both anti-inflammatory and analgesic, largely through its ability to cause vasoconstriction, decrease enzymatic activity, reduce the formation of inflammatory mediators, and slow down nerve conduction. The optimal frequency and duration of cold treatment for musculoskeletal disorders in horses has not been determined. The authors recommend...
20 minutes of cold hosing several times daily during the acute phase of tendon and ligament injuries.

Research data have indicated that cold hydrotherapy is superior to the use of ice packs because of the increased contact and evaporation. It is also less likely to cause adverse effects such as superficial tissue damage and cold-induced nerve palsy. Prolonged exposure to cold temperatures can also cause a reflex vasodilatation, which can accentuate tissue swelling and edema. For this reason, it is recommended not to apply cold therapy for periods longer than 30 minutes. One highly effective way of providing cold hydrotherapy is the use of equine spas, which are currently gaining popularity. They provide both cold and compression using hypertonic saline at 5° to 9° C. In addition to equine spas, underwater treadmills, used as part of controlled exercise programs in tendon and ligament injury rehabilitation, allow conditioning of the musculoskeletal system with minimal concussive forces.

**Compression and coaptation**
In the acute phase of injury, pressure applied to the affected limb reduces inflammation and edema formation by increasing interstitial hydrostatic pressure. A modified Robert Jones bandage is suitable in most cases of acute tendon and ligament injury.

In severe injuries when there is hyperextension of the MCP joint, a palmar/plantar splint or cast may be applied to the bandaged limb to provide MCP joint support (Fig. 86-19). A palmar splint can be fashioned from two rolls of 7.5-cm (5-inch) casting tape. One roll is layered on top of itself over a length that matches the length of the limb from the carpus to the bulbs of the foot. This is placed on the palmar aspect of a 2.5-cm-thick support bandage on the contralateral limb. The contralateral limb can be used as a template for making the splint, since it has the optimal degree of extension at the MCP joint. A second roll is wrapped around the palmar splint and bandage and left to set. The palmar splint is then cut away from the bandage using a cast saw and applied to the palmar aspect of the bandaged affected limb. A similar effect can be achieved more easily with the specially designed boot, although this is not yet available commercially. A full distal limb cast may be used as an alternative in the most severe cases, such as suspensory ligament rupture, when all MCP joint support has been lost.

**Immediate controlled mobilization**
Immediate controlled mobilization of the limb has been advocated in the acute phase of tendon and ligament injury to reduce inflammation and improve healing. This mobilization is obtained by early passive and active movement of the injured tissues. To be successful, the degree or frequency of mobilization must remain below the patient’s pain threshold. The mobilization is administered by a 15 minute session of gentle physical therapy, involving series of 10 to 30 passive carpal and MCP joint flexions, interspersed with short breaks, for the first 72 hours.

**Controlled exercise**
Controlled exercise is an intrinsic part of the rehabilitation of tendon and ligament injuries, helping to resolve residual inflammation, maintain gliding function, and promote optimal collagen remodeling. Most SDFT injuries require at least 8 to 9 months of rehabilitation before resumption of full athletic function, although some may require up to 18 months. It is rarely necessary to prolong rehabilitation longer than this, because healing appears to be complete by this stage.

A suitable exercise rehabilitation program should be created on the basis of the severity of the ultrasonographic appearance of the lesion. The aim of the program is to provide a controlled and ascending exercise regimen that optimizes scar tissue function without causing further injury. Since this is difficult to predict because of variability between animals, the program should be adapted on the basis of serial ultrasonographic monitoring and clinical signs such as lameness, heat, and swelling.

Ultrasonographic monitoring of the tendon or ligament injuries should include measurements of tendon cross-sectional area (CSA). An increase in CSA of greater than 10% between examinations would suggest a degree of reinjury, and in such cases the level of exercise should be reduced. Because there is a sudden increase in strain levels in the SDFT and SL with an upward transition in gait from walk to trot, trot to canter, and canter to gallop, ultrasonographic examinations before and after these transitions can help to determine if the injured tendon or ligament can withstand the increased strain levels.

The importance of a controlled exercise program was illustrated by Gillis, who demonstrated that of 28 Thoroughbred racehorses with SDFT tendinitis placed in a controlled exercise program, 71% returned to racing, compared with only 25% of 8 horses managed with uncontrolled turnout. An example of rehabilitation programs for racehorses and sports horses is shown in Table 86-1.
Extracorporeal shock wave therapy

Extracorporeal shock wave therapy (ECSWT) has been established for a number of years for the treatment of human orthopedic conditions, especially insertional desmopathies. ECSWT involves the use of shock or pressure waves that are transmitted into the tissues to which the hand piece is applied. Both focused and nonfocused units have been used, although the data that compare these machines are too limited to indicate a significant difference. The mechanism of action of ECSWT on tissues is unclear, but it is most likely related to induction of analgesia through an effect on sensory nerves. The most frequently reported use of ECSWT in horses has been for the treatment of proximal SL desmitis, and a significant improvement in prognosis over conservative treatment for chronic hindlimb proximal SL desmitis has been reported. Investigation into ECSWT as a treatment for chronic SL desmitis resulted in 41% of hindlimb cases returning to full work within 6 months of diagnosis, compared with the previously reported 13% for conservatively managed cases.

**Therapeutic ultrasound, laser, and magnetic fields**

The effect of ultrasound, laser, and magnetic fields on tissues is not completely understood. It is thought that the main effect of ultrasound is the conversion of sound energy into thermal energy. Although there is a paucity of scientifically convincing research into the effects of ultrasound for the treatment of equine musculoskeletal disorders, a study by Morcos and Aswad showed that in experimentally split equine tendons, the use of therapeutic ultrasound resulted in increased vascularization and fibroblastic proliferation compared with controls.

Low-level laser (light amplification by stimulated emission of radiation) therapy has been shown to stimulate cellular metabolism and to enhance fibroblast proliferation and collagen synthesis in vitro. However, there are no clinical trials demonstrating a significant difference between laser-treated and control cases of tendinitis or desmitis.

Magnetic therapy has not been demonstrated in any clinical trials to enhance tendon or ligament healing, despite its widespread use by horse owners and anecdotal reports of its efficacy.

**Counter-irritation**

Counter-irritation, in the form of chemical or thermal cauterization, has long been used in equine practice for the treatment of tendon and ligament injuries. Topical iodine and mercury-based compounds have been used for chemical cauterization or “blistering” of tendon injuries. Thermal cauterization (or “firing”) is performed under general anesthesia or standing sedation with local analgesia, using heated bars or pins, which are applied to the skin over the injured tendon or ligament. In some cases, the tendon is penetrated with the heated pins. Studies have shown that there is no histologic difference between the collagen arrangement in the scar in cases of tendinitis treated with firing and that of the controls. It has been postulated that any benefits from firing result from the enforced rest, the local release of inflammatory cytokines, or a protective "bandage" of fibrous tissue or skin that supports the tendon. However, it has been demonstrated that firing causes thinner and weaker skin in the region that was cauterized. The limited controlled studies that have been performed on firing have concluded that it is not an effective treatment for tendon and ligament injuries.

**PHARMACOLOGIC MANAGEMENT**

**Systemic medication**

Both systemic corticosteroids and nonsteroidal anti-inflammatory drugs can be considered for the management of tendon or ligament inflammation in the acute stages. Phenylbutazone is commonly used at a dose of 2.2 mg/kg twice daily, but the clinical effects of this drug appear to be more analgesic than anti-inflammatory. Systemic steroids...
can be administered within the first 24 to 48 hours after injury, but they should be avoided after this time because they also inhibit fibroplasia and hence repair of the tendon. The most commonly used systemic steroid is dexamethasone at 0.1 mg/kg as a single dose. The induction of laminitis with systemic steroids represents a small, but nevertheless real, risk. Topical or intravenous dimethyl sulfoxide (DMSO) may reduce the inflammation, but a study has shown that 40% to 90% topical medical grade DMSO may weaken normal tendon tissue.64

**Intralesional medication**

Various intralesional treatments have been advocated for the management of tendinitis. These treatments include polysulfated glycosaminoglycans (PSGAGs), hyaluronan (HA), and beta-aminopropionitrile fumarate, with recent interest being focused on novel growth factor and cell-based therapies. Intralesional tendon and ligament treatment can be performed under standing sedation and local analgesia, or under general anesthesia. Weightbearing potentially assists injection, since the tendons are then taut. Although the technique is frequently performed blindly, by injecting where the least resistance in the tendon is detected, accurate placement of the needle in the center of the lesion is best achieved using ultrasonographic guidance. The skin overlying the tendon or ligament to be injected should be clipped and aseptically prepared, and if ultrasonographic guidance is used, a sterile sleeve should be placed over the probe. A 2.5-cm, 23-gauge hypodermic needle can be used for most intratendinous treatments, but this depends on the viscosity of the agent. Intralesional treatment should not be administered until 3 days after the injury, because there is the potential to increase hemorrhage. The volume injected into the tendon or ligament will depend on the extent of the lesion. Large volumes can be damaging to the healing tendon.65

PSGAGs have been shown to inhibit collagenases and metalloproteinases and to inhibit macrophage activation,5 but they were shown to have no effect on fibroblasts.66 Hence, this drug can be viewed as a soft tissue anti-inflammatory agent. PSGAGs have been widely used for the treatment of tendinitis and desmitis, both intralesionally and intramuscularly. In one study of 73 horses, treatment with PSGAG either intramuscularly or intralesionally resulted in 76% of horses returning to work versus 46% of the control animals, although these results were not statistically significant.67 Another study demonstrated improved echogenicity of collagenase-induced superficial digital flexor tendinitis treated with intralesional PSGAGs, with faster resolution of core lesions.68 However, Dyson demonstrated no significant difference in reinjury rates between horses treated with PSGAGs and those treated with controlled exercise alone.69

HA consists of repeating units of d-glucuronic acid and repeating units of N-acetyl-d-glucosamine and is a component of the tendon matrix. HA has been administered peritendinously, intralesionally, and systemically to treat tendinitis. A study by Dyson showed no significant difference between the reinjury rates of horses with SDFT tendinitis treated with intralesional HA and those treated conservatively.59 In a study of collagenase-induced digital flexor tendinitis, HA was found to minimize tendon enlargement compared with controls, although histopathologic examination of the tendons failed to demonstrate a significant difference in the degree of inflammation.70 Peritendinous HA has been shown to have no effect on ultrasonographic or histologic appearance, biomechanical properties, or molecular composition of tendons in collagenase-induced tendinitis compared with controls, although it did appear to reduce lameness.71

HA has been shown to decrease the extent of adhesions when administered intrathecally to treat collagenase-induced deep digital flexor tendinitis within the digital sheath.72 Horses treated with intrathecal HA showed decreased inflammatory cell infiltrate and less intratendinous hemorrhage than controls.72

**Methylprednisolone** injected into and around normal equine tendons has been shown to cause dystrophic tissue mineralization and tissue necrosis, most likely a consequence of the carrier.73 Hence, the local use of this steroid should be avoided. Nondepot preparations may be used peritendinously with caution.

Intralesional beta-aminopropionitrile fumarate (BAPN) has been used to treat tendinitis 30 to 60 days after injury. BAPN (derived from *Lathyrus odoratus* [sweet pea]), inhibits the enzyme lysyl oxidase, which normally forms crosslinks between collagen fibers. The rationale for its use is to allow exercise to promote alignment of newly formed collagen fibrils while preventing them from being fixed in a haphazard fashion by crosslinking. BAPN does not hasten the resolution of the tendinitis but aims to improve the structure of the repaired tendon.

Initial studies by Genovese on the effect of BAPN for the treatment of tendinitis demonstrated that 80% of tendons treated with BAPN had normal ultrasonographic echogenicity 20 weeks after injury, compared with only 29% of control cases.74 However, long-term follow-up results of horses with SDFT tendinitis treated with BAPN based on return to racing showed less favorable results: 67% (56/84) of horses returned to racing, with 50% (42/84) of horses racing five times or more.75

Although in collagenase-induced models of tendinitis, both the ultrasonographic appearance76 and the histologic collagen alignment were superior in BAPN-treated horses compared with controls,77 more recent concerns have been raised over its efficacy, based on observations that BAPN reduces collagen synthesis78 and showed no improvement over controls in a rabbit model of tendinitis.79 Nevertheless, Dyson compared the re-injury rate of horses with SDFT tendinitis treated with either BAPN or PSGAGs combined with controlled exercise, with the re-injury rate of controlled exercise alone, and the use of BAPN resulted in a decreased re-injury rate; however, the long-term injury rate of the untreated limb was high.69 On the basis of this information, Dyson recommended treatment of both limbs even if there was no ultrasonographic evidence of tendon damage on the contralateral limb.69 BAPN treatment is most appropriate in cases of severe tendinitis with an extensive core lesion, when there is potentially a greater volume of scar tissue that will be synthesized.

**New advances: Tissue engineering approaches**

The use of *growth factors* is a relatively recent approach. Insulin-like growth factor-1 (IGF-1) has been investigated...
to assess its effect on tendon healing both in vitro and in collagenase-induced models of tendinitis. IGF-1 stimulates extracellular tendon matrix synthesis, and it is also a potent mitogen. In collagenase-induced models of tendinitis, initial swelling was decreased after intralesional injections of IGF-1 compared with controls, although no differences were found at later time points and there was no difference between the quantities of type I and type III collagen synthesized. There are no published long-term follow-up data regarding re-injury rates of tendinitis treated with IGF-1.

Recombinant equine growth hormone administered intramuscularly has demonstrated a negative effect on the biomechanical properties (decreased yield point and ultimate tensile strength) of the SDFT during the early phases of healing in collagenase induced tendinitis. However, these properties were assessed at 6 weeks after treatment, which may have been too soon to detect any beneficial effects.

TGF-β has been considered as another appropriate growth factor treatment, but clinical experience has been limited. Treated horses showed significant enlargement of the tendon and, although re-injury rates were similar to those in conservatively managed horses, these re-injuries were all on contralateral, untreated, limbs.

A Cell Vet is a novel intratendinous treatment for tendinitis using acellular tissue components derived from porcine urinary bladder submucosa. This preparation has been suggested to deliver appropriate growth factors to the injured tissue and to attract mesenchymal stem cells. There is only anecdotal evidence that this treatment improves tendon and ligament healing, and controlled clinical trials are required to further assess efficacy.

Treatment with intralesional bone marrow has been investigated for SL desmitis. The aim was to stimulate ligament regeneration rather than scar tissue formation by the delivery of stem cells to the damaged tendon or ligament. Bone marrow is a rich source of growth factors but contains very few stem cells (1 in 10⁴ nucleated cells). Hence, this treatment more closely resembles a growth factor treatment.

In a survey of clinical cases, 84% of horses treated with intralesional bone marrow were reported to return to the preinjury level of exercise, whereas only 15% of control cases achieved this. However, no information was provided about the specific location of the SL injury, or whether lesions were located in the hindlimb or forelimb, which has a significant effect on prognosis. Furthermore, the large volumes of bone marrow used (30 to 50 mL) and the presence of other cells and material may have deleterious effects on the healing tendon or ligament tissue surrounding the lesion.

The use of autologous mesenchymal stem cells (MSCs) for intralesional treatment of SDFT and SL lesions is currently being investigated. MSCs have the potential to differentiate into tenocytes and to regenerate tendon matrix, thereby creating a repair that is functionally superior to fibrous scar tissue. Initial studies have included the isolation of MSCs from either bone marrow or fat, followed by either direct implantation or expansion of MSC numbers in vitro before implantation. No controlled studies have been published to prove efficacy, although anecdotal clinical evidence has been encouraging.

### Surgical Therapies

#### Tendon Splitting

Tendon splitting was first performed in the 1940s and the technique was published in 1967. It was initially advocated as a treatment for chronic tendinitis to improve blood flow to damaged tendon tissue that is relatively avascular. The technique fell out of favor when subsequent research demonstrated extensive granulation tissue formation, and increased trauma to the tendon tissue and persistent lameness after treatment. Tendon splitting is therefore no longer recommended for the treatment of chronic tendinitis but is now thought to be more relevant to the management of acute cases when there is an anechoic core lesion evident on ultrasonographic examination, indicating the presence of a seroma or hematoma. It has been hypothesized that the presence of a core lesion within a tendon produces a compartment syndrome, resulting in decreased perfusion and ischemia of the region. The aim of tendon splitting in acute cases is therefore to decompress the core lesion by evacuating the serum or hemorrhage and to facilitate vascular ingrowth. Removal of the fluid in the core lesion may also reduce proximodistal propagation of the lesion. In a collagenase-induced model of tendinitis in six horses, tendon splitting using the knife technique resulted in a faster resolution of the core lesion, quicker revascularization of the lesion, and increased collagen deposition than in controls.

Tendon splitting may be performed under standing sedation or under general anesthesia. It can be done blindly or using ultrasonographic guidance, which minimizes damage to normal tendon tissue by enabling the needle or knife to be inserted at a point where the core lesion is closest to the periphery of the tendon. A no. 11 scalpel blade or double-edged blade is inserted into the tendon and “fanned” proximally and distally (Fig. 86-20). Alternatively, the procedure can be achieved with multiple insertions of a 23-gauge needle, possibly with less damage to the remaining, relatively intact, tendon tissue. Furthermore, needle splitting may be combined with various intralesional treatments.

After tendon splitting has been performed, a modified Robert Jones bandage should be applied and the horse rested in a stall for 10 to 14 days, after which a controlled exercise program should be initiated.

#### Desmotomy of the Accessory Ligament of the SDFT

Superior check ligament desmotomy was first described as a treatment for SDFT tendinitis by Bramlage in 1986. The aim of the surgery is to produce a functionally longer musculotendinous unit to reduce strain on the SDFT. However, it has been shown in equine cadaver models that desmotomy of the accessory ligament of the SDFT (DALSDFT) actually increases the strain on the SDFT during loading because of increased extension of the MCP joint. The biomechanical alterations of DALSDFT thus are complex, and studies using cadaver limbs may not represent the biomechanical events in a fatigued galloping racehorse. However, increased risk of injury of the suspensory ligament after the DALSDFT has been performed has also been demonstrated in vivo.

Initial results from Bramlage demonstrated that 79% of horses suffering from superficial digital flexor tendinitis
treated with DALSDFT competed in two races without recurrent tendinitis.90

DALSDFT can be performed with the horse in lateral or dorsal recumbency. A 10-cm skin incision is made between the cephalic vein and the caudal radius on the medial aspect of the limb. The incision should extend from the level of the medial malleolus of the radius, to mid-chestnut proximally (see Fig. 90-14). A transverse branch of the cephalic vein may require ligation to improve access. The cephalic vein is retracted caudally to expose the flexor carpi radialis (FCR) sheath, which is incised to reveal the FCR tendon. The FCR tendon is retracted caudally to expose the accessory ligament of the SDFT, which is located adherent to and deep to the lateral aspect of the FCR sheath. Both the transverse and the deeper oblique fibers of the accessory ligament of the SDFT are transected sharply with or without the assistance of forceps to elevate the latter. Ideally, the artery and vein of the proximal SDFT are identified on the proximal border of the accessory ligament and preserved.93

The FCR sheath and the fascia should be closed in two layers using a simple-interrupted pattern and with 2-0 or 0 synthetic absorbable suture material for each layer (e.g., polyglactin 910). The skin is then closed with a simple-interrupted or vertical mattress suture pattern using 2-0 or 0 nonabsorbable material (e.g., monofilament nylon).

A well-padded bandage capable of providing compression is applied over a sterile dressing for 10 to 14 days to reduce the risk of seroma formation at the surgical site, which is a common complication of this procedure. The initial rehabilitation period involves 2 weeks of stall rest, followed by a controlled exercise program as previously described. More recently, this procedure has been carried out tenoscopically through the carpal sheath.94 With the affected limb uppermost and partially flexed, an arthroscopic portal is created into the carpal sheath 2 cm proximal to the distal radial physis on the lateral side of the limb (Fig. 86-21). An instrument portal is made immediately proximal to the distal radial physis. With the limb in 90 degrees of flexion, the accessory ligament is visualized on the medial aspect of the sheath and cut using a no. 10 scalpel blade on a long handle, or meniscectomy knife. The very proximal portion of the ligament cannot be visualized directly but is transected by careful dissection using punch biopsy forceps, taking care to avoid the perforating blood vessel at the proximal limit of the accessory ligament.

**TENOSCOPY**

The increasingly widespread use of tenoscopy has demonstrated a high frequency of intrathecal tendon tears that are associated with tenosynovitis and lameness. Hence, horses presenting with tenosynovitis with pain on palpation of the proximal digital sheath and lameness should always be considered candidates for tenoscopic evaluation. Based on a recent survey of cases, tears in the DDFT are more commonly found in forelimb digital sheaths, whereas tears to the manica flexoria are more commonly found in hindlimbs (Fig. 86-22). Ultrasonographic evaluation usually reveals nonspecific changes of synovial hypertrophy, and it is frequently not possible to identify tears on ultrasonographic examination with confidence. However, when a tendon tear extends into the center of the tendon, it can be identified as an anechoic lesion (since it is filled with synovial fluid). Manica tears are particularly difficult to identify ultrasonographically, but occasionally disruption of the attachment of the manica to the SDFT can be demonstrated. In addition, tears can also be found and debrided tenoscopically in the SDFT and in the distal sesamoidean ligaments within the digital sheath. Tears of other tendons and ligaments communicating with a synovial cavity have been seen to be associated with synovial distention and lameness (e.g., in
the suspensory ligament branches into the MCP/MTP joint (see Fig. 86-16). Tenoscopy of the digital sheath requires general anesthesia and can be performed in lateral or dorsal recumbency. However, dorsal recumbency allows easier access to both sides of the digital sheath and is recommended. Arthroscopic portals are created immediately distal to the proximal sesamoid and 1 to 2 cm palmar/plantar to the neurovascular bundle (Fig. 86-23). This allows evaluation of the proximal and distal parts of the digital sheath, although distal visualization can sometimes be easier with the arthroscope inserted through a portal in the proximal digital sheath (e.g., as for a proximal instrument portal). Instrument portals are created where appropriate to allow débridement of any tendon tears with a mechanical resector. This may require the instrument portals to be extended through the synovial reflection that attaches to the proximal border of the manica flexoria to allow access to DDFT tears located within or proximal to the manica. Although manica tears can also be débrided as is done for DDFT tears, this has been associated with poorer outcome than complete removal. As no adverse effects have been observed with complete removal, this is recommended for all but the most minor manica tears. Removal requires transection of both medial and lateral attachments to the SDFT, as well as transection of the synovial attachment to the proximal border of the manica. This is facilitated by an assistant who maintains tension on the manica with rongeurs through the contra-axial proximal instrument portal. Transection can be achieved with arthroscopic scissors, bistoury, or a hook knife.

Figure 86-21. Site for tenoscopic transection of the accessory ligament of the superficial digital flexor tendon (superior check ligament desmotomy). a, arthroscopic portal; b, egress/instrument portal; c, accessory ligament of the tendon of the superficial digital flexor muscle; d, tendon of the lateralis digital extensor muscle; e, tendon of the ulnaris lateralis muscle; f, tendon of the deep digital flexor muscle; g, radial head of deep digital flexor muscle; h, superficial digital flexor muscle. (From Southwood LL, Stashak TS, Kainer RA: Tenoscopic anatomy of the equine carpal flexor synovial sheath, Vet Surg 1998;27:152.)

Figure 86-22. Common abnormalities detected as causing tenosynovitis of the digital sheath. A, Surface tear of the deep digital flexor tendon, most commonly found in forelimb tenosynovitis. B, Rupture of the attachments of the manica flexoria, most frequently seen in hindlimb tenosynovitis.
Chronic tenosynovitis can be associated with synovial masses attached to the synovial plicae in the proximal digital sheath. These, together with isolated adhesions, can also be resected during tenoscopic evaluation and the palmar or plantar annular ligament transected if it is believed to be involved in the pathology (Fig. 86-24). Postoperatively, the horse should be strictly rested for at least 2 weeks, after which hand-walking can be started and gradually increased over a period of at least 6 weeks. Thereafter, the duration of rehabilitation depends of the severity of the injury. The prognosis for simple DDFT tears (about 40%) is worse than for simple manica tears (about 80%).

Figure 86-23. Tenoscopy of the digital sheath, now a routine procedure. A, The original description was in lateral recumbency, and the arthroscope was introduced into the digital sheath immediately distal to the palmar annular ligament, 1 to 2 cm palmar to the neurovascular bundle. B, However, dorsal recumbency allows more flexibility to evaluate both sides of the digital sheath and easier bilateral approach for surgical removal of the manica flexoria. (From Nixon AJ: Endoscopy of the digital flexor tendon sheath in horses, Vet Surg 1990;19:267.)

Figure 86-24. Tenoscopic resection of an adhesion. If adhesions are isolated findings (A), they can be removed using a mechanical resector (B). Care should be taken to avoid disrupting large areas of the synovium, or adhesion formation may be even more exaggerated after surgery.
ANNULAR LIGAMENT DESMOTOMY

Annular ligament desmotomy has been advocated for the management of DDFT and SDFT lesions in the region of the MCP and MTP joints. The procedure is indicated if the annular ligament is impeding the normal gliding function of the flexor tendons. Annular ligament desmotomy is performed under general anesthesia and is ideally performed tenoscopically using a hook knife with or without a slotted cannula (Fig. 86-25), rather than via closed or open techniques, because it is less traumatic, ensures accurate transection of only the palmar or plantar annular ligament, and allows evaluation of the tendons to identify any surface defects. For a more detailed discussion of annular ligament desmotomy and its indication, please review Chapter 94.

FASCIOTOMY AND NEURECTOMY OF THE DEEP BRANCH OF THE LATERAL PLANTAR NERVE FOR THE TREATMENT OF PSLD

Surgery has been advocated in cases of proximal suspensory ligament desmitis (PSLD) of the hindlimb that are unresponsive to conservative management. It has been reported that horses have returned to high-level competition after tibial neurectomy to treat PSLD. However, a more specific neurectomy of the deep branch of the plantar nerve has recently been described. This is performed under general anesthesia with the horse in dorsal recumbency. A 4- to 6-cm incision is made adjacent to the lateral border of the SDFT, originating proximally from the level of the chestnut (Fig. 86-26). The plantar metatarsal fascia is incised and the incision extended deep to the SDFT by blunt dissection, facilitated by retraction of the SDFT. The lateral plantar nerve is located in connective tissue, the deep branch is identified and transected using a scalpel, and a 3-cm section is removed. The connective tissue fascia covering the suspensory ligament is cut (fasciotomy) adjacent to the lateral splint bone to decompress the origin of the suspensory ligament, since hindlimb proximal suspensory desmitis is believed to be associated with a compressive compartment syndrome involving the plantar metatarsal nerves.

Postoperatively, only a short period of strict rest is needed (about 2 weeks) to allow the surgical incisions to heal. Thereafter, the horse can gradually begin a controlled ascending exercise program. Nonpublished reports have suggested that this technique is associated with a high level
of success in returning affected animals to full work with minimal risk of exacerbating the desmitis.

ACCESSORY LIGAMENT OF THE DDFT DESMOTOMY/DESMECTOMY
Conservative treatment is usually successful for the treatment of accessory ligament of the DDFT (ALDDFT) desmitis. However, in some cases, desmitis may be recurrent or cause adhesions between the ALDDFT and the SDFT, or a flexural deformity. In such cases desmotomy, or preferably desmectomy, of the accessory ligament of the DDFT can be considered.

ALDDFT desmotomy is performed under general anesthesia in lateral recumbency. The ALDDFT can be approached medially or laterally. A medial approach results in improved cosmesis but an increased risk of vascular damage to the medial palmar artery, and the lateral technique has the opposite effect. After aseptic preparation of the surgical site, a skin incision is made in the proximal half of the metacarpus adjacent to the palmar border of the DDFT (see Fig. 90-11). The incision is continued deeper by blunt dissection to expose the ALDDFT. The ALDDFT is elevated using forceps and is transected with a scalpel. Greater exposure can allow complete removal of the accessory ligament if necessary. The wound is closed in two layers—first, the fascia with a simple-continuous pattern using an absorbable suture material, and second, the skin. A modified Robert Jones bandage should be applied to the distal limb postoperatively for 3 to 4 days.

Tendon Lacerations
Lacerations of the digital extensor tendons can result in the partial or complete loss of protraction of the distal limb, or the animal may place the limb in an abnormal position (Fig. 86-27). However, many cases show minimal signs. In contrast, horses suffering from flexor tendon lacerations are usually in severe pain and need immediate attention.

Emergency Treatment of Tendon Lacerations
The limb should be stabilized before the horse is moved to an appropriate place for treatment. It is important that the limb be supported to ensure the comfort of the horse by restoring some biomechanical function of the limb and to prevent further tissue damage. It is particularly important to avoid further trauma to the neurovascular structures of the distal limb. For flexor tendon lacerations, a palmar or dorsal splint or a commercial splint (e.g., a Kimsey splint [see Fig. 78-4]) should be applied. Any difficulty in limb protraction with an extensor tendon laceration can be managed with a simple splint bandage. For more information on the first aid of traumatized horses, review Chapter 78.

Surgical Repair
FLEXOR TENDONS
Surgical repair of flexor tendon lacerations involves débridement, suturing of the tendon, and closure of the wound and is usually performed under general anesthesia in lateral or dorsal recumbency. The aims of tenorrhaphy are to restore tendon gliding function, minimize gap formation between the tendon ends, minimize adhesion formation, and preserve functional vasculature. If the laceration is complete, the tendon may have recoiled, requiring proximal and distal extension of the skin wound in an elongated S shape to locate both tendon ends (Fig. 86-28). Flexing of the MCP/MTP joint may facilitate locating the distal tendon end. The wound and tendon ends should be débrided and lavaged. If the tendon ends can be apposed, tenorrhaphy can
be performed using a monofilament absorbable suture (e.g., polydioxanone or polyglyconate). Nonabsorbable materials should be avoided, since they can result in shearing between the healed tissue and the suture material and may be responsible for persistent lameness. Two suture patterns are commonly used, the three-loop pulley and the interlocking loop (Fig. 86-29). The three-loop pulley prevents distraction of the ends of the tendon under loading (i.e., gapping), whereas the interlocking loop has little suture material outside the tendon and is therefore the recommended technique for repair of intrathecal lacerations. The interlocking-loop pattern can be supplemented with simple-continuous sutures to reduce gap formation between the tendon ends. A single locking-loop suture is not as strong as a double- or triple-locking loop or a three-loop pulley pattern.10 0

Frequently the injury is associated with significant blunt trauma to the tendon ends, which precludes direct apposition of the tendon ends. In this situation, the tendon ends can be left after débridement, the wound closed, and the limb cast, or an implant can be used to maintain the alignment of the tendon ends. The ideal tendon implant material would have biomechanical properties similar to those of normal tendon. Various implant materials have been used to repair lacerated flexor tendons including carbon fiber, terylene (polyester), autologous extensor tendon grafts, and poly-L-lactic acid (PLLA).101 Carbon fiber implants were associated with persistent lameness postoperatively, which may have been caused by tenalgia resulting from shear forces between inelastic carbon fibers and the healed tendon tissue. The use of autologous grafts using extensor tendons to bridge the deficit between two ends of a lacerated tendon has never gained popularity. The advantage of PLLA is that it supports fibroblast growth on its surface and loses its strength over several months, thereby being able to match its mechanical properties with the tendon. Implants are anchored in each end of the lacerated tendon by fixing the ends in V-shaped incisions created in the tendon ends with sutures of monofilament absorbable sutures. Implants are not recommended as a treatment for strain-induced tendinitis.

Partial lacerations involving less than 50% of the tendon may need only local débridement. Lacerations involving greater than 50% are probably best sutured, since this can prevent the generation of longitudinal splits between loaded and unloaded parts of the tendon.

Flexor tendon lacerations require a protracted rehabilitation period. A distal limb cast should be placed with forelimb lacerations postoperatively. In the hindlimb, a full-limb cast is required after flexor tendon laceration to immobilize the forces of the reciprocal apparatus. However, distal limb casts can be used in the hindlimb to avoid the increased risk of complications of full-limb casts, unless an implant has been placed, in which case the result is usually that one end is pulled out of the tendon. Casting is required for a minimum of 6 to 8 weeks and no more than 12 weeks, thereby often necessitating one cast change under general

---

**Figure 86-29.** A, A modified compound locking-loop suture pattern. Bites perpendicular to the tendon fibers are superficial relative to bites that are aligned parallel to the fibers. B to E, The three-loop pulley suture pattern with each loop oriented 120 degrees relative to the others. The first loop is in a near-far pattern (B), the second loop is equidistant from the transected ends (C), and the third loop is placed in a far-near pattern (D and E). (From Watkins JP: Tendon and ligament disorders. In Auer JA, Stick JA, editors: Equine Surgery, ed 2, Philadelphia, 1999, WB Saunders.)
anesthesia, as studies have shown that the breaking strength of the tendon repair at 6 weeks approximates the bodyweight of the horse. Support of the MCP/MTP joint using a palmar/plantar splint with a modified Robert Jones bandage and caudal shoe extensions (for DDFT lacerations) can help protect the repair after cast removal. Continued box stall rest is necessary for a further 2 to 3 months, after which walking exercise followed by an ascending exercise regimen can be initiated. Ultrasonographic monitoring of tendon healing is useful to assess the integrity of the tendon repair. A minimum of 8 to 12 months is usually required before full athletic function can be resumed.

The prognosis for flexor tendon injuries is guarded, with approximately 45% of horses returning to athletic function in one study; in another study, the prognosis was 59% for flexor tendon lacerations. In the second study, the prognosis for return to soundness was not increased if the DDFT and SDFT were simultaneously lacerated compared with involvement of only a single structure. Complications of tendon lacerations include necrotic tendinitis (which occurs as a result of infection or damage to the vascular supply), concurrent synovial sepsis, cast complications, adhesions resulting in continued pain and lameness, exuberant granulation tissue formation, flexural deformity, and re-injury.

EXTENSOR TENDONS

Extensor tendon lacerations heal remarkably well without tenorrhaphy and respond well to conservative management. The wound should be debrided and the primary wound closed if appropriate. If the extensor tendon has been lacerated within the confines of a tendon sheath (e.g., for extensor lacerations over the dorsal aspect of the carpus), the area should be lavaged, and elimination of sepsis from the tendon sheath needs to be addressed. Fibrous scar tissue gradually forms an attachment between the two tendon ends. A period of 4 to 6 weeks of box stall rest until the wound has healed is usually all that is required. A cast can be used to assist soft tissue healing if contusion has been extensive. The prognosis for extensor tendon lacerations is good, with about 72% of horses returning to athletic function, and other sources report an 80% good prognosis. The prognosis for extensor tendon lacerations is better than for flexor tendon lacerations because the extensor tendon bears considerably less load and has a minimal effect on the gait, with most protraction of the limb and digit arising from the upper limb and momentum of the foot. Indeed, a recent publication reported the successful management of septic common digital extensor tenosynovitis by complete resection of the tendon. Stumbling may be evident at the walk until the tendon has healed, but this can be reduced by shortening the toe of the hoof and rolling the toe of the shoe or by fitting a Natural Balance type of shoe. If extension cannot be maintained spontaneously, a toe extension can be fitted to the shoe to prevent secondary contracture, although this may make stumbling more severe.

The most common complications associated with extensor tendon lacerations include exuberant granulation tissue and sequestrum formation associated with underlying damage to the bone, although acquired flexural deformities can occur.

STRUCTURE AND FUNCTION OF MUSCLES

Of the three types of muscle in the body—skeletal, smooth, and cardiac—skeletal muscle makes up about 40% of the body weight. All movement is the result of contraction of skeletal muscle, and most patients with neuromuscular disease exhibit abnormal movement. Skeletal muscle consists of a central fleshy muscle belly and a tendon at each end. The tendon at one end of the muscle originates on one bone, and the tendon at the other end inserts on a different bone, with a movable joint interposed. When activated by a motor neuron, a skeletal muscle can only contract (or shorten). Movement occurs when the central muscle belly shortens, causing the two tendons and their bones of attachment to move with respect to each other around a central joint. A muscle returns to its original longer length by the pull of its antagonistic pair, a muscle that traverses the joint on the opposite side. Some muscles increase joint angle (extensors), and some muscles decrease joint angles (flexors).

Anatomy

Skeletal muscle has several levels of organization (Fig. 87-1). Each muscle belly is made up of thousands of muscle cells (also called muscle fibers). Each muscle fiber contains thousands of myofibrils that are arranged in parallel along its length, and each myofibril is made up of a series of repeating sarcomeres. The sarcomere is the basic contractile unit of the muscle fiber.
Myofibrils have an arrangement of alternating thick and thin filaments. The thick filaments are composed of the protein myosin, and the thin filaments are composed of the proteins actin, tropomyosin, and troponin. Myofibrils are surrounded by membranes in the form of tubules. These tubules are composed of a transverse tubular system and the sarcoplasmic reticulum, and collectively they are called the sarcotubular system. Each muscle fiber is innervated by a terminal branch of a motor nerve fiber. The junction between the nerve and the muscle fiber is the neuromuscular junction. All muscle fibers that are innervated by a single nerve fiber are called a motor unit because all of the muscle fibers within a unit are excited simultaneously and contract in unison.

**Physiology of Contraction**

It is at the neuromuscular junction that action potentials are generated. The resting membrane potential of the sarcolemma is excited by a synaptic transmission at the neuromuscular junction. Via transverse tubules, the action potential reaches the sarcoplasmic reticulum throughout the muscle fiber. Skeletal muscle cells (muscle fibers) convert chemical energy into mechanical energy. At rest, calcium ions are maintained within the sarcoplasmic reticulum of the muscle cell. The arrival of an action potential to the sarcoplasmic reticulum causes the release of calcium ions. These calcium ions perfuse the sarcomere and bind with troponin. This alters the actin filament, allowing it to react with the myosin filament. Although a detailed molecular explanation of the sliding filament mechanism is not known, the altered actin molecule is now able to slide along the myosin molecule, causing a physical shortening of the sarcomere (Fig. 87-2). As the action potential passes, calcium ions are returned to the sarcoplasmic reticulum, allowing the sarcomere to relax.

![Figure 87-2](image)

**Figure 87-2.** The sliding of actin along the myosin molecule results in the physical shortening (contraction) of the sarcomere. (From Cunningham JG: Textbook of Veterinary Physiology, ed 3, Philadelphia, 2002, WB Saunders.)

Therefore, in the presence of calcium ions and ATP, actin and myosin molecules slide over one another. This results in a physical shortening of the sarcomere and ultimately of the myofibril and the muscle belly. The cumulative effect of a shortened sarcomere is a reduction in the distance between the two tendon ends, and their bones of attachment move with respect to each other around a central joint.

Adenosine triphosphate is needed for this contraction, and creatinine phosphate can be used to replenish ATP stores from ADP. The enzyme creatine phosphokinase (CPK) catalyzes this conversion and is found in high concentrations within muscle cells. During muscle cell damage, the CPK that is normally contained within intact muscle cells can leak into the bloodstream. Therefore, identification of an abnormally high concentration of serum CPK is used routinely to assess skeletal muscle necrosis. Muscle contraction is only about 40% efficient in converting chemical energy to mechanical energy, and most of the energy is lost as heat. This phenomenon is exploited during shivering to raise core body temperatures. During shivering, antagonistic muscle groups are activated so that they produce no useful work. The chemical energy lost as heat is transferred to the body core to increase temperature.

**Muscle Repair**

Muscle has a very limited capacity for regeneration. In some muscles, stellate cells have been identified that can form new muscle fibers. For practical purposes, however, new muscle fibers are not formed after birth. Enlargement and growth of muscle occur via enlargement of fibers caused by formation of additional myofibrils. Repair of damaged muscle occurs by replacement with connective tissue. Muscle has a good blood supply and a ready source of fibroblasts. Healing of damaged muscle with scar tissue is usually rapid, but replacement of damaged muscle with large amounts of scar tissue can restrict muscle length and function.

**SPECIFIC MUSCLE DISORDERS**

**Fibrotic Myopathy**

The classic description of fibrotic myopathy is that of a unilateral hindlimb gait abnormality, in which the cranial phase of the stride is shortened and there is a rapid caudal movement of the limb during the caudal phase of the stride as the foot slaps the ground (Fig. 87-3). This condition is most evident when the horse is observed at the walk from a lateral perspective. The overall prevalence of the disease is low: of the 167,132 horses examined by 22 university veterinary hospitals in North America over the 10 years from 1979 to 1988, 102 horses (0.06%) were diagnosed with fibrotic myopathy.

**Pathophysiology**

In most horses, traumatic injuries that cause adhesions and fibrosis of the semitendinosus muscle are responsible for the condition. Less commonly, injury to the semimembranosus, biceps femoris, and gracilis muscles have been identified. Trauma may result from lacerations, slipping while exercising, and entrapment of a foot in halters, lead shanks, or fences. In one study, 5 of 18 horses with fibrotic
myopathy developed the condition secondary to intramuscular injections. Tearing the insertion of the semitendinosus muscle during activities that create extreme tension on the caudal aspect of the hindlimb (barrel racing, the slide of a reining horse) has also been incriminated. The characteristic gait of horses with fibrotic myopathy can occur temporarily after transportation in a trailer; in this case, it is caused by a localized myositis of the semitendinosus muscle because of prolonged pressure by the rear rope or bar on the muscle. Fibrotic myopathy in the neonate is speculated to be caused by trauma at or soon after birth, although the exact etiology is unknown in congenital cases. Horses born with the gait characteristic of fibrotic myopathy have a taut semitendinosus muscle and tendon, but they do not have palpable fibrosis of the muscle. In a small series of horses, traumatic or degenerative neuropathy causing denervation of the distal fibrosis of the muscle. In a small series of horses, traumatic or degenerative neuropathy causing denervation of the distal semitendinosus muscle because of prolonged pressure by the rear rope or bar on the muscle. The limb is jerked backward just before hitting the ground.

Figure 87-3. Motion of the rear limb of a horse affected with fibrotic or ossifying myopathy. The limb is jerked backward just before hitting the ground.

Diagnosis
The diagnosis of fibrotic myopathy is made by observing the abnormal gait and by palpating the fibrotic or ossified muscle areas. Lameness is usually most apparent at the walk and is characterized by an abrupt cessation of the cranial phase of the stride of the affected limb, with the foot suddenly jerked caudally just before it hits the ground (see Fig. 87-3). This gait abnormality is not painful and is caused by mechanical restriction (either fibrous or osseous) of the affected thigh muscles. The gait abnormality is evident on every stride, is nonresponsive to analgesics, and is not altered by manipulative tests.

The fibrotic or ossified areas of the affected muscles may be palpated on the caudal aspect of the thigh at the level of the stifle joint or immediately above it. Ultrasonography may be helpful in defining areas of fibrosis, whereas radiography is more useful to demonstrate areas of ossification.

Treatment
Several surgical procedures for the correction of this disorder have been described. These techniques include semitendinosus myotomy, semitendinosus myotenectomy, or semitendinosus tenotomy at the tibial insertion of the muscle.* Earlier treatments described for these conditions include resection of the fibrous or ossified part of the semitendinosus muscle and removal of adhesions to surrounding muscles. Myotomy and myotenectomy are no longer recommended because of the relative high rate of postoperative complications, including prolonged hemorrhage, wound dehiscence, high recurrence rate, and noncosmetic outcomes.

Semitendinosus tenotomy is presently the treatment of choice for fibrotic myopathy of the semitendinosus muscle. This procedure is performed under general anesthesia in lateral recumbency with the affected limb down, providing access to the medial aspect of the tibia. Landmarks for surgery include the tibial insertion of the muscle on the caudomedial aspect of the tibia just distal to the medial femorotibial joint and caudal to the saphenous vein overlaying the gastrocnemius muscle. An 8-cm vertical skin incision is made directly over the palpable tendon, and through the subcutaneous and crural fascia until the tendon is exposed. A large forceps, such as a curved Kelly or Crile, is passed under the tendon to isolate it from the muscle, and the tendon is transected (Fig. 87-4). Resection of a 3-cm segment of the tendon may delay recurrence of the gait abnormality. Facial layers are closed with interrupted or continuous synthetic absorbable sutures, and the skin is closed with interrupted or continuous nonabsorbable suture material.

When the affected limb is pulled forward during surgery, the tendon of insertion of the semitendinosus muscle onto the calcaneal tuber may become very taut in some horses. An additional 3- to 4-cm-long incision has been recommended directly over the taut tendon, which is then isolated and transected. This incision is caudal and slightly distal to the first incision. Tenotomy is technically easier than the other procedures and eliminates an incision into diseased muscle.

Prognosis
With myectomy and myotomy, improvement is usually noticed immediately, but it may take up to 7 days for maximal improvement. Standing myotomy resulted in partial recurrence of the gait abnormality after surgery in approximately one third of 39 horses treated. An additional 3- to 4-cm-long incision has been recommended directly over the taut tendon, which is then isolated and transected. This incision is caudal and slightly distal to the first incision. Tenotomy procedure alone results in fewer complications than the other techniques, including less predisposition for reformation of the fibrous band, but it may not result in complete resolution of the gait abnormality.* If a degenerative neuropathy is the cause of the condition, recurrence of clinical signs is likely, regardless of the surgical technique employed.

Stringhalt
Stringhalt is a hindlimb gait abnormality characterized by involuntary and exaggerated flexion of one or both

*References 3, 5, 6, 8, 10, 11.
During the cranial phase of the stride, the limb is jerked toward the abdomen (Fig. 87-5). There may be a wide variation in the severity of the signs that occur during every walk stride. The gait abnormality has a classic appearance, but it should be differentiated from mild forms of intermittent upward fixation of the patella. The patella catches on the medial trochlea of the distal femur in intermittent upward fixation of the patella, and when it releases it gives the appearance of a horse with stringhalt.

Pathophysiology

Two forms of stringhalt have been described: a conventional (sporadic) form and an Australian (outbreak) form. In North America, the disease is usually seen as the sporadic form; it involves a single hindlimb and occurs as isolated cases. In Australian and New Zealand, the disease is usually observed in both hindlimbs and occurs epidemiologically. The occurrence of conventional stringhalt is rarely seen as a bilateral condition. The cause has been attributed to an overextension injury of the tarsus and metatarsus; metatarsal, tarsal, and stifle injuries; foot pain; spinal cord disease; and tendon adhesions. Although the true etiology for the condition is unknown, sporadic stringhalt is suggested to be caused by an underlying neuropathy. One author reports that all muscle or peripheral nerve isolates from horses with sporadic stringhalt had histologic evidence of neuropathy or degenerative myopathy. This form of stringhalt usually has not been associated with the spontaneous recovery that is seen in the Australian form.

Australian stringhalt is recognized predominantly during the summer or fall in horses on pasture, and it often follows drier-than-normal summer months. Its etiology has been clearly shown to involve an underlying neuropathy. Although the toxic principle is not known, it occurs in groups of horses on pastures containing dandelions known as flatweeds (Hypochoeris radica). Evaluation of nerve samples from horses with Australian stringhalt has demonstrated widespread neuropathy. Lesions occur in the left recurrent laryngeal nerve in approximately 60% of these horses. The lameness in Australian stringhalt is caused by a peripheral neuropathy and neurogenic muscle atrophy of the long digital extensor, lateral digital extensor, and gastrocnemius muscles. Many horses recover without treatment.

Diagnosis

The diagnosis is based on observation of the characteristic gait caused by exaggerated flexion of one or both hindlimbs. The abnormalities are usually bilateral in Australian stringhalt. The onset is often sudden. Some horses show a very mild flexion of the hock during walking, and others show a marked jerking of the foot toward the abdomen, with the foot actually hitting the abdomen in severe cases (see Fig. 87-5). The abnormal gait is usually evident with each step. Rest and cold weather tend to accentuate the gait, and in some horses, the gait may return to normal with exercise. All breeds can be affected.

Treatment

Horses with Australian stringhalt often recover spontaneously. Removal from the incriminated pasture may be curative, although recovery can take from months to years and may not be complete. In one study, 78% of the horses recovered over a period ranging from a few days to more than 18 months. Although surgical treatment is not recommended for horses with Australian stringhalt, good results were recently reported in 11 horses. Five horses were able to walk normally immediately after the surgery (described later) in both hindlimbs, whereas only partial improvement was noted immediately postoperatively in the remaining six horses. Five of them resumed a normal gait in 4 to 12 weeks.
postoperatively. The last horse suffered a relapse several weeks postoperatively and eventually recovered spontaneously 9 months after surgery. Because conventional stringhalt is rarely associated with spontaneous recovery, lateral digital extensor tenectomy and partial myectomy is the treatment option for these horses.

The objective of lateral digital extensor (LDE) tenectomy and partial myectomy is to remove the distal 2 to 10 cm of the LDE muscle, and the entire tendon, from the muscle to its attachment to the long digital extensor tendon. The procedure may be performed using local anesthesia when removing small portions of muscle belly, or under general anesthesia when removing large portions of the muscle belly. For the standing procedure, a 2-cm line of local anesthetic is injected over the LDE tendon just proximal to its junction with the long digital extensor tendon on the lateral aspect of the metatarsus. This site is easily palpable just below the tarsometatarsal joint. Local anesthetic also is infiltrated directly into the muscle belly of the LDE, about 2 cm above the lateral malleolus of the tibia.

The distal incision is made directly over the tendon just proximal to its junction with the long digital extensor tendon. The tendon is subsequently exposed by bluntly dissecting beneath the tendon with a curved Kelly or Ochsner forceps. The proximal incision is located on the lateral aspect of the limb approximately 6 cm above the lateral malleolus of the tibia. It extends through the skin, subcutaneous tissue, and fascia directly over the lateral digital muscle in a vertical direction, parallel with the muscle fibers. The muscle belly is exposed using blunt dissection, and a heavy curved instrument is placed underneath it (Fig. 87-6).

Before severing the tendon, the surgeon should ensure that the tendon in the distal incision corresponds to the muscle belly in the proximal incision. The tendon is severed in the distal incision and is pulled through the tendon sheath by traction on the proximal portion with a curved Ochsner forceps or Mayo scissors. Removing the tendon from its sheath is a maneuver that requires substantial force, particularly if adhesions are present. After the entire length of the tendon has been exteriorized, the muscle is severed at the proximal aspect of the incision, thereby ensuring that at least 2 cm of the muscle is removed.

The heavy fascia of the proximal incision is closed with a simple-interrupted or continuous pattern of no. 0 synthetic absorbable suture material. The subcutaneous tissue is closed with 2.0 synthetic absorbable suture using a simple-continuous pattern, and the skin is closed with nonabsorbable suture material in a simple-continuous pattern. The distal incision is closed with skin sutures only. The wounds are covered with a sterile dressing, and the entire limb is bandaged for 10 to 14 days to control seroma formation. The horse is confined to a stall for this time, after which the sutures can be removed. The horse is then given 1 week of controlled hand-walking, and normal exercise can resume 3 to 4 weeks after surgery.

Complications of surgery include dehiscence; infection, which may enter the open tendon sheath of the LDE tendon; and failure of improvement of the lameness.

**Prognosis**

The prognosis for Australian stringhalt is fair. Many horses recover spontaneously, although a few have stringhalt of such severity that they are euthanized. The prognosis for conventional stringhalt is guarded to favorable, because surgery is unpredictable and can result in partial to complete recovery. Many horses show improvement after surgery, but the degree of improvement varies from slight to a complete remission. Improvement may occur immediately or take several months.

**Peroneus Tertius Disorders**

The peroneus tertius is an entirely tendinous muscle. It originates in the extensor fossa on the cranial lateral aspect of the distal femur with the long digital flexor tendon. It courses distally over the cranial aspect of the tibia, and it divides distally into branches that surround the tendon of insertion of the tibialis cranialis muscle. At the dorsal aspect of the tarsus, it divides into a lateral branch that inserts on the calcaneal and fourth metatarsal bones, and a medial branch that inserts on third metatarsal and third tarsal bones. The tarsocrural joint is actively flexed by the contraction of the tibialis cranialis muscle and the passive pull of the tendinous peroneus tertius muscle. The peroneus tertius is an important part of the reciprocal apparatus of the hindlimb, which coordinates flexion of the hock and stifle (see Figs. 99-2 and 99-3).

Injury to the peroneus tertius is a relatively rare condition that has been reported in two locations: avulsion at the origin (most commonly seen in foals), and in the distal third of the body (most commonly seen in adults). It has been speculated that foals may be more likely to suffer...
avulsion injuries as a result of inherent weakness in their bones.22

Pathophysiology

By virtue of the anatomy described earlier, flexion and extension of the tarsus and stifle must occur simultaneously. Rupture of the peroneus tertius tendon is usually the result of overextension of the tarsus with normal stifle flexion. This may occur when the horse slips with a hindlimb extended backward, during the exertion of a rapid start, or when the limb is trapped and the horse struggles to free it.24 A full limb cast extending to the proximal tibia may cause rupture if the horse slips with the leg extended behind, or struggles against the cast.4

Diagnosis

Although the peroneus tertius tendon may rupture anywhere along its length, it does so most commonly in the distal third of the tibia just proximal to the tarsus. The classic sign of a complete rupture is the ability to extend the hock while the stifle is flexed. A characteristic dimple forms in the common calcaneal tendon on the caudal lateral aspect of the crus, just proximal to the calcaneal tuber (Fig. 87-7). When standing, the horses may bear weight normally, but during the caudal phase of the stride during the walk or trot, the distal limb appears abnormally flaccid. With avulsion injuries, horses can be severely lame initially, and there may be accompanying distention of the femorotibial and femoropatellar joints.22,23 In the acute phases of a rupture, digital palpation may reveal some swelling and pain in the craniolateral aspect of the crus, but typically there is little or no evidence of pain.

When the horse is walked, the tarsus may be noted to extend more than usual, and at the trot the horse is seen to be severely lame. A delay in the cranial phase of the stride can be easily identified because of an inappropriate degree of extension in the tarsus. Although there are usually no radiographically apparent signs of rupture, the peroneus tertius tendon is the most echogenic structure on the craniolateral aspect of the crus, and it is readily identified by ultrasonography. Radiography is necessary for diagnosing avulsion fractures.

Treatment

Horses with avulsion injuries of the origin of the peroneus tertius muscle are best evaluated arthroscopically.22,23 Small bone fragments can be removed, but large bone fragments that are encapsulated by the joint capsule are better left in place. Six weeks of stall rest followed by controlled exercise for 3 months is recommended.

Peroneus tertius rupture is best treated with 3 months of restricted exercise in a box stall. Resumption of exercise starting with hand-walking usually results in a total resolution of clinical signs, and surgical intervention is unnecessary.

Prognosis

Horses with avulsion injuries have a guarded prognosis for full soundness, but successful outcomes have been reported.22,24 Minor disruptions may heal, but outcomes are contingent on concurrent injuries. Most horses with ruptures of the body are able to return to full athletic function.24,25

Rupture of the Extensor Carpi Radialis Tendon

Rupture of the extensor carpi radialis tendon is usually the result of a traumatic insult, such as a kick or laceration at the distal cranial aspect of the radius, stumbling and falling on a road (coronation), or contact between a forelimb and a sharp object.

Diagnosis

Horses suffering from a rupture of the extensor carpi radialis tendon have a peculiar gait. Protraction of the involved forelimb results in hypermetric elevation, because the flexor muscles are not opposed by their main antagonist, the extensor carpi radialis muscle (Fig. 87-8). Palpation of the cranial aspect of the carpal and distal radial region reveals a defect in the area of the missing tendon. In cases with a laceration, the distal tendon stump is often seen in the injury site.
Treatment
Lacerations should be carefully debrided and closed, and a drain should be placed for the initial few days. If possible, the tendon should be repaired with three-loop pulley or a locking loop technique (see Fig. 86-29). The laceration should be sutured using routine wound repair techniques and the limb placed in a splint bandage that prohibits carpal flexion for 6 weeks. The bandage should be changed after 3 days and the drain removed. The horse is restricted to a box stall and the splint bandage is changed at regular intervals. If no open wound is present or the wound does not involve the sheath of the extensor carpi radialis tendon, the tendon is not sutured, but the limb is kept in a splint bandage for 6 weeks, followed by bandaging the limb for an additional 3 weeks. Hand-walking is initially the only exercise, and it is gradually increased. Local wound management should be applied to superficial wounds.

Prognosis
Generally, a good prognosis for return to a successful athletic career is given for rupture of the extensor carpi radialis tendon. Complications include infection of the tendon sheath and dehiscence of the sutured tendon or sutured laceration. In such cases, conservative management involving daily wound care and bandage changes is required. The prognosis in complicated cases is guarded for return to an athletic career.

Cribbing and Aerophagia
Etiology
Cribbing or crib biting in the horse is a vice characterized by the placement of the upper incisors on a solid object, arching the neck, depressing the tongue, elevating the larynx, and pulling backward.26-35 If the horse swallows air, the process is called aerophagia, or “wind sucking,” and an audible grunt can be heard. The sequelae to this habit are poor performance, weight loss, erosion of the incisors, and chronic colic. The principal reason that horses with this vice are presented to a veterinarian is because the behavior is objectionable and irritating to owners, and it results in an unacceptable level of property destruction. The habit is learned or acquired and is usually associated with stalled horses, although once learned it can continue in the pasture. Another reason patients are presented is that pressure is exerted on the owner by owners of horses stabled in the same barn, who are afraid their horses will acquire the vice.

Removing fixed objects that are grasped while cribbing may deter horses that have just learned the vice. Management changes rarely deter horses with established habits, some of which are capable of aerophagia without grasping a fixed object. Cribbing straps are perhaps the most common nonsurgical means used to control cribbing or windsucking. Leather straps with or without a ventrally located piece of articulating metal are placed snugly around the throatlatch of the horse to discourage contraction of the ventral neck muscles and arching of the neck. More severe straps have metal prongs that pierce the skin when the neck is flexed. Cribbing straps are adjusted to allow the horse to eat and breathe normally and are worn at all times except during exercise. Acupuncture may be useful for eliminating or decreasing cribbing and aerophagia.25 Aversion (shock) therapy has also been used to treat horses that crib.22

Surgical Management
Three surgical procedures are described for the control of cribbing and aerophagia: the Forssell procedure, a modified Forssell procedure, and bilateral neurectomy of the ventral branch of the spinal accessory nerve.26,28,32,35 The original procedure was developed by Dr. Forssell in 1920 and involves the surgical removal of portions of the sternomandibularis, sternothyrohyoideus, and omohyoideus muscles.26,32,33 A modification of Dr. Forssell’s original surgery, developed to produce a better cosmetic appearance, is the treatment of choice for wind sucking when used in combination with neurectomy.28 The technique of bilateral neurectomy of the ventral branches of the spinal accessory nerves (11th cranial nerves) is modified from the technique described by Hamm.31 The ventral branches provide motor innervation to the sternomandibularis muscles, which are the major muscles used by the horse to flex its neck. Because of the poor results achieved with this procedure alone, it is now described as a part of the modified Forssell procedure.28

Modified Forssell procedure
The horse under general anesthesia is placed in dorsal recumbency with the head tilted at a 30-degree angle to the horizon.20 After surgical preparation, a 30-cm incision is made on the ventral midline of the neck through the skin, the edges of which are retracted laterally, exposing the ventral surface of the paired bellies of the omohyoideus and the sternothyrohyoideus, and the cranial aspect of the sternomandibularis muscle. Careful attention to hemostasis minimizes staining of the areolar tissue and thus simplifies identification of the nerve. A plane of dissection is created on the medial aspect of the sternomandibularis muscle about 5 cm caudal to the musculotendinous junction. The ventral branch of the spinal accessory nerve is located on the dorsomedial aspect of this muscle by carefully rolling the muscle belly laterally. Curved hemostatic forceps are placed under the nerve, which is elevated until a sizable portion of it can be exteriorized. Contraction of the muscle after the nerve is pinched with hemostat forceps confirms isolation of the correct nerve. A large portion (6 to 12 cm) of nerve is removed. This same procedure is then repeated on the opposite side of the neck.

After the bilateral neurectomy, the myectomy is performed. A 30-cm section of the combined bellies of the omohyo-
drain is removed 4 to 6 days later, followed by the skin sutures 10 to 14 days postoperatively. Exercise can be resumed after 21 days. Hematomas or seromas, although rarely encountered, can be managed conservatively or by drainage. Antibiotic therapy initiated preoperatively can be applied until the drain is removed.

**Prognosis**

The modified Forsell procedure produces a good cosmetic appearance after surgery, and rapid healing of the wound. A review of 35 horses that underwent the modified Forsell procedure revealed that 57% had complete remission, 31% had improvement, and 12% had no improvement.

**Calcinosis Circumscripta**

**Pathophysiology**

Calcinosis circumscripta (tumoral calcinosis) is an uncommon condition that is identified more commonly in the young horse. Although the etiology of these lesions is unknown, it has been suggested that prolonged repeated trauma may be the cause. These horses have normal serum calcium and phosphorus concentrations. Histologically, these masses are calcified granular amorphous material that induces a fibrous reaction. They are surrounded by a thick fibrous capsule that contains deposits of gritty material. They are typically located in the subcutaneous tissue close to joints or tendon sheaths. The lateral aspect of the stifle adjacent to the fibula is an area of predilection, although they also can be found on the dorsal lateral aspect of the tarsus, and around the neck and shoulder. In 14 affected horses, the characteristic feature was a 3- to 12-cm dense subcutaneous mass located at the lateral aspect of the gaskin, adjacent to the stifle.

**Diagnosis**

Rarely is lameness or pain associated with the condition. Typically, these horses present for cosmetic reasons and do not have any lameness. Owners notice an unsightly lesion that may be increasing in size. Lesions are usually hard, are occasionally bilateral, are well circumscribed, do not involve the overlying skin, and are tightly adherent to the underlying tissue. Radiographs demonstrate a circumscribed mineralized tissue lying close to the lateral aspect of the femorotibial joint with a density that is similar to that of cortical bone.

**Treatment**

Treatment is indicated only if the cosmetic appearance is unacceptable to the owner, or if there is lameness caused by the mass. When required, surgical excision is the recommended treatment option. Attention to aseptic technique is imperative, since some masses attach to the femorotibial joint capsule, which may be accidentally entered during surgery. Closing dead space during surgery, and snug limb bandages or stent bandages will prevent postoperative seroma formation, since wound dehiscence and septic arthritis are potential complications.
Prognosis
For horses that are not treated, the mass remains and may not cause complications. A good result can be expected after surgical excision, and regrowth has not been reported. Wound healing is important if the joint capsule is entered during surgery.

REFERENCES
Orthopedic infection is a more serious clinical problem in horses than in many other species, because its consequences can induce permanent lameness and result in loss of use of the horse or in death. Infection in a joint causes severe inflammation that can lead to irreversible cartilage damage and continued degeneration of the joint even after the infection is resolved.¹,² Pain from osteoarthritis causes lameness in many other species, because its consequences on the normal limb eventually result in failure of the fracture to heal.³ It is difficult to rigidly immobilize fractured bones with available implants in an animal the size of a horse. The combination of infection and minor movement at the fracture usually results in failure of the fracture to heal and ultimately to humane destruction of the horse. The treatment of orthopedic infection in horses is also more difficult because of the high incidence of laminitis in the opposite limb from increased weightbearing while the infection is being treated. Chronic increased weightbearing on the normal limb eventually results in failure of the laminae in the foot, laminitis, and separation of the distal phalanx from the hoof wall. Laminitis may occur at any time during treatment and can result in treatment failure even when the infected fracture heals or the joint infection resolves.

The treatment of orthopedic infection in horses has greatly improved over the last 20 years. Early recognition, improved methods of delivering high concentrations of antibiotics to the site of infection,⁴⁻⁹ and techniques used to achieve effective drainage¹⁰ have improved the clinician's ability to successfully eliminate the infecting bacteria. The prognosis for a horse with a septic joint to return to athletic function is no longer hopeless.¹,¹⁰ Despite the advances in treatment, limitations persist. Not every infection can be eliminated, and complications such as opposite-limb laminitis because of delayed fracture healing still result in death of the animal. In addition, the cost of treating horses with orthopedic infection is high. In a review of 38 horses with fractures that developed infection after surgical repair, the average duration of hospitalization was 142 days.¹¹ The costs of hospitalization and treatment make humane destruction the treatment of choice for some horse owners. However, the treatment of orthopedic infection has been successful even in complicated cases, and euthanasia should be considered only after treatment options have been explored, many of which were not considerations 20 years ago.

Clinical Signs
Bacterial invasion of a joint induces rapid pathologic changes¹²⁻¹⁴ that result in joint effusion and severe lameness. The degree of lameness varies depending on the size of the horse (foals typically bear some weight on the limb), the duration of the infection, and the pathogenicity of the infecting organism. Some horses may walk almost normally, whereas others support little or no weight on the affected limb. Distention of the involved joint is a consistent sign that can be detected visually, by palpation of the joint pouches, or both. In some horses, increased joint fluid may not be detectable because of overlying soft tissues (i.e., at the shoulder) or the small size of the joint capsule (i.e., at the distal two tarsal joints). Periarticular edema, cellulitis, or both may make palpation of joint effusion difficult. Horses with a joint infection have pain on palpation and usually respond to digital pressure applied over the joint capsule. Horses with open joint lacerations through which synovial fluid is draining are frequently not as lame as horses with closed joint infections.

Horses with septic arthritis usually have a fever at some point after the initial infection. However, fever may not be present, especially if the animal has been treated or placed on nonsteroidal anti-inflammatory medication. On the other hand, fever is one of the earliest and most consistent observations in horses that develop an infection after joint surgery. In a retrospective study of 25 horses with postoperative joint infection, a body temperature above 39°C (101°F) was the most consistent clinical observation and appeared at an average of 9 days after surgery.²

Diagnosis
A diagnosis of septic arthritis or synovitis is confirmed by obtaining fluid for cytology and analysis. Synovial fluid is obtained through arthrocentesis using aseptic technique. Synovial fluid from infected joints averages a total white
blood cell (WBC) count of more than 75,000 cells/dL, predominantly neutrophils, and contains more than 5 g/dL total protein. Normal synovial fluid has fewer than 300 cells, fewer than 10% neutrophils, and less than 2.5 g/dL protein. When the gross appearance of the synovial fluid is cloudy or turbid, infection is likely. A total WBC count of less than 10,000 cells/dL does not rule out an infected joint; some joints have relatively low WBC counts because of sequestration of the WBCs within fibrin deposits in the joint. One of the most consistent findings in the synovial fluid is a shift to more than 80% to 90% neutrophils.

Bacteria may be seen during cytologic evaluation, but only 24% of fluid samples have bacteria observed on a direct smear. Although chemical irritants injected into a joint may cause similar abnormalities in the synovial fluid, there are few, if any, other causes of these synovial fluid abnormalities in horses. Immune-mediated inflammatory arthropathies are rare in horses but should be considered in adult animals with multiple affected joints. Horses exhibiting the described abnormalities in their synovial fluid analysis and cytology should be treated as if they have a septic joint or tendon sheath until proven otherwise.

Before treating a horse with an infected joint or tendon sheath, it is important to obtain a sample of synovial fluid for culture. Synovial fluid is aspirated and placed in blood culture medium. Ideally, 5 mL is obtained for culture, but any volume that is aspirated is used. The use of blood culture techniques maximizes the chance of incubating the infecting organism or organisms and obtaining antimicrobial sensitivity results, which help in the selection of effective antimicrobial drugs. There is no advantage to obtaining a synovial membrane biopsy for culture because bacterial isolation rates in clinical cases and experimental trials have been as high or higher with synovial fluid. If the horse has been previously treated with antibiotics, obtaining synovial fluid for culture is still recommended, although the presence of antibiotics decreases the chances for a positive culture. It is important to list the type of antibiotic used on the laboratory request form. In joints with a small volume of fluid, such as the tarsometatarsal joint, it may be necessary to first inject the joint with sterile saline before a sample can be aspirated for culture.

Radiography
Radiographic examination is recommended for every horse with an infected joint or tendon sheath to evaluate the bones for signs of osteitis or osteomyelitis and to rule out fractures and associated joint pathology. This is essential in foals and horses with chronic joint infections. The presence of osteomyelitis in subchondral epiphyseal bone or in the physis in foals complicates treatment and may decrease the prognosis for soundness based on the anatomic location (e.g., beneath a weight-bearing articular surface). The subchondral bone and, in young horses, the surrounding physis should be evaluated for local bone lysis (Fig. 88-1).

Treatment
Aggressive and early treatment is recommended to eliminate an infection in synovial structures as soon as possible. Treatment is always initiated before culture results are known. Because in 25% of synovial fluid samples, an organism may not be isolated, it is important to aim antimicrobial therapy at the most likely infecting organism using broad-spectrum antimicrobial agents. The source of the joint infection should be considered. Horses that develop sepsis after surgery or intra-articular injection are likely to be infected with staphylococcus, especially Staphylococcus aureus. Horses that develop infection after a wound are more likely to have an Enterobacter species isolated from the synovial fluid; cultures from these joints frequently have multiple organisms identified, including Staphylococcus, Streptococcus, Pseudomonas, and anaerobes. The most common bacteria isolated from a group of equine orthopedic patients in one hospital were Enterobacteriaceae, Streptococcus, Staphylococcus, and Pseudomonas, in decreasing order of incidence. Broad-spectrum bactericidal drugs should be administered by the intravenous route to maximize penetration into the synovial fluid.

In addition to efficacy against the most common bacterial isolates, expense of the drugs is a factor in selecting antibiotics. Cefazolin and amikacin may not be affordable at systemic doses in every patient, despite their broad spectrum and efficacy against isolates from horses with infected joints. Penicillin and gentamicin are less expensive and still effective against many bacteria. Ceftiofur and cefazolin are antibiotics with a broad spectrum of efficacy and could be considered for initial intravenous antibiotic treatment.

Joint Lavage
Joint lavage is indicated in horses and foals with a septic joint. The decision to perform the lavage through needles or under arthroscopic guidance is usually based on the duration of the infection and the severity of the clinical signs. Acute cases may respond well to a through-and-
Intra-articular Antibiotics

The intra-articular administration of antibiotics is a routine treatment in horses with septic arthritis. Gentamicin achieves high synovial fluid concentrations with relatively low intra-articular doses (150 mg) and causes minimal inflammation. Amikacin, because of its similarity to gentamicin and its efficacy against a wide range of bacteria, has become a routinely used intra-articular antibiotic. Cefitiofur, Timentin (ticarcillin-clavulanic acid), methicillin, and imipenem-cilastatin can be injected into joints with few inflammatory side effects on equine synovium. Imipenem-cilastatin, which is a suspension when 500 mg is diluted in 10 mL of sterile saline, causes only mild inflammation when it is injected once daily for 3 days. Cefazolin injected into equine patients with septic arthritis causes no observed ill effects. The number of antibiotics that can be safely used intra-articularly will continue to increase; however, it is important that antibiotics be evaluated for their inflammatory effects on joint tissues before they are used in clinical patients. Some antibiotics may cause damage to the synovium or articular cartilage, or both. Synovial fluid levels measured after intra-articular injection of gentamicin, ceftiofur, ticarcillin-clavulanic acid, or Primaxin (imipenem-cilastatin) are 10 to 100 times the synovial fluid levels that can be achieved with systemic administration. Organisms identified as resistant with antimicrobial susceptibility techniques used in the laboratory may be susceptible to the high concentrations of antibiotic achieved with intra-articular injection. Care must be taken not to exceed systemic doses of antibiotics in horses with multiple septic joints or tendon sheaths. This is most likely to occur in young foals with a relatively small body mass and multiple affected joints, especially because these foals receive systemic antibiotic therapy as well. Intra-articular antibiotics are usually administered after a joint lavage, and then once a day until clinical signs are resolving. Amikacin is the most frequently used intra-articular antibiotic because of its efficacy. The use of the correct intra-articular antibiotic makes a dramatic difference in the clinical response to treatment. However, drugs such as ticarcillin-clavulanic acid and Primaxin should not be used routinely, to decrease the chances that bacteria will develop resistance to these antibiotics.

Regional Limb Perfusion

Another method that is used to deliver high concentrations of antibiotics to the joint and surrounding bones and soft tissues is regional limb perfusion. The technique uses the vascular space to maximize antibiotic penetration into the synovial fluid and also into the tissues around the joint. It is of particular value in foals when penetration of bone and surrounding soft tissues is needed in sites of bacterial colonization. In the author's experience, it has been particularly valuable for treating foals that have osteomyelitis in the physis or epiphysis of hematogenous origin. The technique does not achieve synovial fluid concentrations as high as can be obtained through direct injection into the joint space, but synovial fluid levels exceeding 55 times the minimal inhibitory concentration (MIC) reported for most organisms can be reached with gentamicin. Gentamicin concentration remains at or above the MIC for most sensitive organisms 24 hours after perfusion.

Regional limb perfusion is performed by placing a tourniquet on the limb proximal to the area to be perfused. For the carpus and tarsus, a tourniquet also is placed distal to these joints. One gram of amikacin is diluted in 120 mL of sterile saline and injected through an intravenous catheter.
placed into a peripheral vein distal to the tourniquet using sterile technique. The tourniquet is maintained on the limb for 20 minutes to allow time for the antibiotic to penetrate into the synovial fluid, bone, and soft tissues. Antibiotics that have been used for this procedure in our hospital in addition to amikacin are gentamicin (500 mg), imipenem-cilastatin (250 mg), and cefotaxime (500 mg). Original studies performed with 300 mg of gentamicin have shown that a relatively small dose of antibiotics achieves high concentrations of the drug in the synovial fluid. The procedure is frequently performed under general anesthesia after lavage of the joint. However, it can be performed on the distal limb of adults and in foals under sedation with local anesthesia.

Regional limb perfusion can be considered in any horse with a septic joint. It is recommended in horses that have cellulitis and edema around the joint and especially in cases where there is osteomyelitis. Penetration into bone using this technique has been shown to be just as effective as an intraosseous injection of antibiotics. Perhaps more important has been the observation that a higher synovial fluid concentration of gentamicin is obtained by intra-articular injection than by regional limb perfusion. Therefore, intra-articular injection of antibiotics is still the most effective way to obtain high synovial fluid concentrations of antibiotics.

Open Drainage

In horses that do not respond to treatment or have a chronic infection, open drainage of the joint is indicated. Clinical signs are used to monitor the response to treatment. Swelling around the joint decreases, the joint effusion resolves, there is less sensitivity to palpation, and the horse’s use of the limb improves when the infection is being effectively controlled. The body temperature returns to normal, and systemic spread of the infection to another synovial structure is unlikely. This is especially important to monitor in young foals. The clinical signs persist or recur in joints where the infection is not controlled.

Open drainage is usually accomplished with the horse under anesthesia and using large-volume (3 to 5 L) lavage of the joint. Two or more 3- to 5-cm arthrotomy incisions are made to allow fibrin and fluid to drain from the joint. The arthrotomy incisions are left open so that chronic and effective drainage of the joint can be achieved, and they are placed in the best location to allow drainage, which varies with the joint. Each arthrotomy is made sufficiently large to allow drainage without becoming sealed by fibrin and local swelling around the incision. Open arthrotomy incisions are protected by a sterile bandage that is changed daily. For joints such as the stifle, which cannot be bandaged, stent bandages may be sutured over the arthrotomy sites, especially in foals. Adult horses are cross-tied or tied to an overhead cable to keep them from lying down. The tail is wrapped, and the incisions are cleaned several times a day.

Open drainage and systemic antibiotics may be sufficient to resolve some infections, but usually, intra-articular antibiotics and repeated lavage of the joint are necessary when treating chronically infected joints. Repeat joint lavage is usually performed with the horse standing and sedated. The decision to perform a repeat lavage is based on examination of the joint. If effective drainage does not occur, the joint becomes distended, the arthrotonmy plugs with fibrin, and the bandage or limb is not soaked by draining fluid. If this occurs, joint lavage through a large-gauge needle placed on the side of the joint opposite the incision allows fibrin to be flushed through the arthrotomy, opening the incision and promoting future drainage. Aseptic preparation of the skin is necessary both at the arthrocentesis site and around the arthrotomy. Distention irrigation of the joint is best accomplished with a 60-mL syringe and an extension tube connected to the needle. The syringe generates considerable pressure that can be controlled and regulated by the volume injected. Fibrin can be removed from the arthrotomy site with a sterile Kelly forceps. Intra-articular antibiotics are injected into the joint after the lavage. Joint lavage is performed only if necessary to maintain effective drainage from the joint. Antibiotics are injected through a small (18- to 20-gauge) needle placed in a location removed from the arthrotomy site under aseptic conditions once a day. Alternatively, a small sterile catheter may be passed into the joint through the arthrotomy once the incision has been cleaned with an antiseptic. It is important to pass the catheter several centimeters into the joint to keep the antibiotics from running back out of the joint immediately after injection.

When infection is eliminated, swelling and effusion resolve, and the synovial fluid draining through the incision becomes clear and viscous. The horse is maintained on systemic antibiotics until the arthrotomy heals. Once the infection resolves, the arthrotomy incision can be closed; the arthrotomy wound is debrided while the joint is lavaged and the incision is sutured closed. Infection resolved after open drainage and closure of the arthrotomy in 30 horses. However, recurrence of infection has occurred in one horse 2 weeks after the arthrotomy was sutured. Early closure of the incision decreases hospitalization and the time that the horse must be on antibiotics with the joint protected by a bandage. However, the risk of recurrence of infection has devastating consequences to the horse and the owner because of the cost of starting over in the treatment of an infected joint.

Penrose drains can be used to improve drainage through openings in joints or tendon sheaths, but Penrose drains are foreign material, do not always contribute to effective drainage, and may be a pathway along which bacteria can migrate into the synovial cavity. Suction drains achieve more effective decompression of a joint through constant suction. Suction drains have been used to successfully treat horses with septic arthritis of the tarsocrural joint. However, closed suction drains are more difficult to maintain than an open arthrotomy incision; they must be protected by a bandage, and the suction device must be continually monitored. Disconnection of the tubing could lead to ingress of air into the joint.

Which treatments are the most effective in eliminating infection in horses with septic arthritis is difficult to determine. Arthrotomy and open drainage decrease fibrin accumulation in the joint in both experimental and clinical cases of septic arthritis. Intra-articular injection of antibiotics has improved success in treating horses with infectious arthritis. It is possible to eliminate joint infection in adult horses with a one-time lavage of the joint followed by daily intra-articular injections of antibiotics,
without administration of systemic antibiotics (because of economics). It is not recommended that systemic antibiotics be eliminated from the treatment regimen for horses with septic arthritis. However, in the future, early administration of intra-articular antibiotic treatments may be all that is necessary to eliminate infections in adult horses with a septic joint. Systemic antibiotics would appear to be necessary for all foals with infectious arthritis to avoid hematogenous dissemination of the infection to another synovial structure.

**Adjunctive Treatment**

Infection in a joint causes the release of most known mediators of inflammation and many catabolic enzymes from degenerating neutrophils that are part of the immune response. After the elimination of the infecting organism, anti-inflammatory medication returns the joint to normal and minimizes damage to the articular cartilage. Hyaluronan, polysulfated glycosaminoglycan (Adequan), and corticosteroids have beneficial effects in inflamed joints. The immunosuppressive properties of both glycosaminoglycan and cortisone increase the risk of recurrence of the infection if even a small number of bacteria have persisted in the joint. Use of these drugs is controversial. The author uses hyaluronan IV (Legend) intra-articularly if all signs of the inflammation and cortisone increase the risk of recurrence of the infection if even a small number of bacteria have persisted in the joint. Use of these drugs is controversial. The author uses hyaluronan IV (Legend) intra-articularly if all signs of the infection have resolved. This appears to help resolve the synovitis and joint capsule thickening that occur in infected joints.

**Septic Physitis in Foals**

Infection of a physis can occur simultaneously or secondary to infection of the synovial space in foals with hematogenous septic arthritis. Septic physitis may also occur as a primary disease, secondary to septicemia in foals, and must be considered a primary differential diagnosis for septic arthritis or tenosynovitis in young foals. Foals with septic physitis have significant lameness, local heat and swelling around the growth plates, and intermittent fever. Because the physes are located near joints, careful palpation of the limb is necessary to distinguish physeal infection from septic arthritis.

Treatment of foals with septic physitis is different from treatment of foals with septic arthritis, because high concentrations of effective antibiotics must be achieved in the physis to successfully resolve infection at this site. The first and most important step in treating foals with septic physitis is to obtain a culture. A relatively easy method of obtaining a culture from an infected physis is to place a large-gauge needle (14 or 16 gauge) into the area of osteomyelitis that is identified on radiographs. In horses with large areas of lysis, purulent exudate may be obtained. Even in foals with a relatively small area of infection, an aspirate of blood can be obtained using suction from a 6-mL syringe; even small aspirates of blood can result in a positive culture.

Once a sample is obtained for culture, regional limb perfusion is performed. This is an effective method of achieving high concentrations of antibiotics in the physis. Although long-term systemic antibiotics also can be effective, a better response has been observed in foals treated with regional limb perfusion. The perfusion procedure is usually repeated at least two more times at weekly intervals; it can be repeated more frequently if necessary based on the clinical and radiographic evaluation of the foal. Although surgical drainage of purulent exudate is recommended, surgical curettage of the physis should be avoided to minimize irreversible damage to the growth plate. The use of regional limb perfusion has decreased the need to débride the area of bone infection and has proven to be an effective method of treatment for foals with septic physitis.

**Prognosis**

The survival rate and return to athletic use of horses with septic arthritis when treated aggressively have greatly improved. In a retrospective study of 192 treated horses, 85% of adults survived and more than 50% of the racehorses (Thoroughbred and Standardbred) returned to racing. This is a significant improvement over prognoses that were given as recently as the early 1980s. With improved techniques and early treatment, the prognosis may be even better. The prognosis is not significantly affected by the joint involved, although one study pointed out the difficulty in treatment of septic arthritis of the distal interphalangeal joint. Tendon sheaths have a better prognosis for survival than joints, perhaps because cartilage damage is not an issue in tendon sheaths. Although the chances for survival are better for a horse with an infected tendon sheath, these horses frequently develop fibrosis within the sheath that limits a return to soundness. The prognosis for foals is less than that of adults (62% survival) because of complications associated with septicemia and multiple-organ involvement. Therefore, treatment of foals is frequently more involved than treatment of a septic joint alone.

Despite improvements in management, not every horse with a joint infection can be successfully treated. Some joint infections are difficult to eliminate, and with time, either the bone is penetrated and osteomyelitis develops or irreversible damage to articular cartilage is caused, resulting in osteoarthritis. Laminitis in the opposite foot also complicates treatment. Some horses with refractory joint sepsis are candidates for arthrodesis, depending on the joint involved and the intended purpose of the horse. For horses with refractory joint infection, euthanasia may be the best option for the owner because of the costs and risks involved with further treatment.

**ORTHOPEDIC INFECTIONS**

Nothing complicates the treatment of a horse after surgical repair of a fracture or arthrodesis of a joint more than infection. Infection after these procedures increases the costs of care, decreases the use of the limb (which increases the chance for laminitis in the opposite limb), and delays healing of the fracture or arthrodesis. The combination of infection and instability of an internal fixation is a reliable recipe for failure. Therefore, every precaution should be taken to decrease the incidence of infection. Once it occurs, early recognition and aggressive treatment are necessary. In the 1970s, when internal fixation techniques were first applied to fractures in horses, infection of a major fracture repair almost always resulted in the death of the horse. Now, some horses with infected fractures can be saved, although treatment is expensive.
Etiology
Infection of a fracture site that has been surgically repaired occurs through an open wound in the skin before surgery, contamination of the surgery site during the open repair, or contamination through the surgical incision. The surgical incision is a source of contamination; excess swelling or motion leads to sutures cutting into the skin, allowing bacteria to invade and colonize the superficial tissues and facilitating the progress of infection deeper into the incision to colonize the implants, fracture site, or joint space. This is an important pathway for infection to invade the fracture site in horses, because there is relatively little soft tissue overlying the bones and joints in the distal limbs. Therefore, surgical incisions should always be protected by sterile bandages and dressings. The limb should be immobilized if the incision is located over a high motion area that will create tension on the sutured skin. Maintenance of a clean, dry seal of the surgical incision is important to avoid complications from infection.

Open fractures or the presence of even a small skin wound over the surgery site is a concern because contamination of the fracture site is difficult to avoid. These cases present difficult treatment decisions requiring experience and judgment regarding the initial treatment and the timing of any attempt at surgical repair. Despite the best decisions made or treatments implemented, treatment failure and loss of the horse may eventually occur.

Clinical Signs
Infection of a fracture site is not always recognized, especially when the incision is under a cast. The earliest and most consistent sign is a low-grade persistent fever observed even if the horse is receiving phenylbutazone. The development of a high fever of 39°C to 40°C within the first 14 days after surgery is also a sign that infection may be present. In a review of 38 horses that developed infection after fracture repair or arthrodesis, the first clinical sign was a temperature elevation above 39°C that occurred an average of 10 days after surgery. Therefore, an increased temperature is an indication to change the cast to allow examination of the incision and the surgical site.

Frequently, horses that develop infection decrease their use of the limb. This is variable and difficult to assess in horses that have a fracture or joint stabilized with internal fixation, because these horses already have reduced use of the limb. Pointing of the cast or injured limb, increased time lying down, increased pawing with the cast, an increase in hyperextension of the opposite fetlock joint, or an increase in ease of displacement of the limb from under the horse when the limb is in a weight-bearing position are all signs of the horse’s decreased comfort on the operated limb. However, some horses that develop infection do not decrease their use of the repaired limb, making accurate recognition of the presence of infection even more difficult.

Evaluation of surgical incisions that are not covered by a cast is important. Horses that develop infection have increased swelling and heat at the surgery site. The skin frequently appears reddened or pink and may start to thin out as the infection progresses (Fig. 88-2). The sutures typically cut into the skin, and there may be drainage through the incision or along the sutures. Depending on the location of the incision, partial dehiscence may occur, with drainage of exudate. Early problems, such as drainage of serum through the incision, increase the risk of infection extending to the implants. An incision may drain a small amount of clear serous or serosanguineous fluid without developing infection; however, there is a higher incidence of infection in these horses than in horses in which the incision remains dry and sealed. An early sign of infection at the surgery site is an accumulation of fluid that can be detected through palpation. The surgical incision should be examined at every bandage change, especially in horses that develop an increased temperature, with the examiner wearing sterile gloves.

Diagnosis
The most important step in recognizing that infection has occurred is to avoid denial. Because of the severe consequences of infection, it is easier and more optimistic to blame the elevation in temperature on a respiratory infection or other causes. However, early recognition is mandatory for successful management.

A complete blood count (CBC) demonstrating a leukocytosis with a neutrophilia confirms that infection is present, but a normal CBC does not rule out infection. A sample of fluid discharged from the wound or aseptically aspirated from deeper accumulations should be analyzed for cytology. A large number of neutrophils (more than 90%), bacteria, or both on a stained smear of the fluid confirms that infection is present. The continued production of excess fluid within or through the surgical wound is evidence that infection is present, especially if it is associated with a body temperature elevation.

Samples should be obtained for culture to identify the infecting organism or organisms and to perform antimicrobial sensitivity testing. If there is fluid accumulation, a needle aspirate can be obtained for culture using aseptic procedures.
tissues. Once infection is confirmed, drainage is usually necessary to resolve the infection. In horses under anesthesia, it is possible to obtain tissue, bone, or a metal implant from the fracture site for culture. However, in a review of cultures from 38 horses, the culture results from swabs and fluid were very similar to results obtained from submitting bone or tissues from deep within the wound. Samples should be submitted for both aerobic and anaerobic culture. It is difficult to accurately identify all of the infecting organisms because of bacterial adherence to the foreign material implant (plates and screws) and their production of a glyocalix that protects them from the wound environment.

**Treatment**

Although systemic antibiotics help control infection, they cannot eliminate infection from surgical sites where infection exists around metal implants. Bacteria secrete a glyocalix (slime) that covers and protects them from antibiotics, antiseptics, antibodies, phagocytes, and mechanical removal by lavage solutions. This is one reason why lavage with antiseptic (povidone-iodine) or antibiotic solutions has not been successful in eliminating infection in horses with infected orthopedic implants. Removal of the implant is usually necessary to resolve the infection. Because of delayed healing, infection frequently causes lysis of bone and loosening of the implants or failure of the fixation from cyclic loading before healing occurs or laminitis develops in the opposite foot. This has made the treatment of infected fractures in horses a difficult and frequently unrewarding experience.

The new approach to horses that develop infection after the repair of a fracture or fusion of a joint is to achieve effective drainage and to maximize the concentrations of antibiotics at the surgery site and in the surrounding tissues. Once infection is confirmed, drainage is usually established by removing a few of the sutures from the bottom of the incision and creating an opening to the joint or fracture site. When the incision has healed or when preservation of the integrity of the suture line is desired, a 3- to 5-cm skin incision is made away from the incision to provide drainage from the surgery site. The incision is continued through any overlying soft tissues until drainage from the implants, fracture site, or joint has been established. Once there is an opening, antibiotic-impregnated polymethylmethacrylate (PMMA) implants are placed into the surgical wound, most frequently along the implants. If the infection is in an arthrodesed joint, antibiotic-impregnated PMMA implants may also be placed into the joint space or pouch. The wound is subsequently covered with a sterile bandage or a cast, depending on the location and orthopedic problem being treated. An antiseptic or antibiotic ointment is usually applied over the wound.

Antibiotic-impregnated PMMA has been used to treat infection in human orthopedic patients for years, and there has been considerable research evaluating the technique. The antibiotic is released from the PMMA over time and achieves high concentrations of antibiotics locally at the fracture site and in surrounding tissues. Depending on the antibiotic, effective concentrations are maintained for many weeks (with gentamicin, concentrations are maintained for many months). The use of antibiotic-impregnated PMMA has improved the treatment success of orthopedic infection in horses. Before the use of this technique, successful treatment of infected fractures was rarely possible. Because of the persistence of infection deep within the fracture, removal of the implants was necessary to eliminate it. Several horses that developed infection after surgery have had the infection resolved without removal of the implants after treatment with antibiotic-impregnated PMMA. This type of management has not eliminated infection in every case, and treatment failures still occur, but it has successfully eliminated infection in some horses. If signs of infection are not resolving, PMMA implants with different antibiotics should be considered. PMMA implants can be removed and replaced in most locations without too much difficulty. The use of other biomaterials (some absorbable) impregnated with antibiotics is described in Chapter 82.

Opening an incision or creating an opening through the skin to achieve drainage can be accomplished with sedation in many standing horses. The skin is desensitized with local anesthetic and prepared for aseptic surgery before making the incision. The more proximal the surgery site is on the limb, the easier it seems to be to establish drainage and insert the PMMA implants without general anesthesia.

Antibiotic-impregnated PMMA can be prepared at the surgery table or before surgery and sterilized with ethylene oxide. If the implants are gas sterilized, it is important to adequately aerate the implants before placing them in a wound. It is best to use a powdered form of the antibiotic to ensure equal mixing and distribution within the PMMA. The antibiotic (powder or liquid) is thoroughly mixed with the powdered polymer before acrylic resin is added (reagent-grade gentamicin in powdered form is available). Usually, 1 to 2 g of antibiotic is combined with 10 g of PMMA powder (1:10 or 1:5 ratio). Addition of antibiotic to PMMA weakens the biomechanical strength of PMMA. This is not an concern where it is being used as a carrier for the sustained release of antibiotic, but it may be a consideration if PMMA is being used to lute plates, where the biomechanical behavior of the material is important. After mixing, liquid resin is added to the powder and stirred. Within a few minutes, the material forms a thick liquid to claylike consistency. When it becomes like clay, the PMMA is rolled into beads and cylinders (Fig. 88-3). The PMMA is allowed to harden (3 to 5 minutes) before the cylinders or beads are implanted into the surgery site. The disadvantages of beads are that they are difficult to remove if the infection resolves and they become incorporated in the fibrous scar tissue. Cylinders of varying lengths (0.5 cm to several centimeters) are easier to remove (if necessary). PMMA implants can be saved and gas sterilized (by ethylene oxide) for future use.

Antibiotics selected for use in PMMA must be heat stable and released from the acrylic into surrounding tissues and fluids. Gentamicin, amikacin, cefazolin, tobramycin, and enrofloxacin have been used by the author in horses with orthopedic infection. With the exception of enrofloxacin, release of these antibiotics from PMMA has been demonstrated in the medical literature.
Antibiotic-impregnated PMMA has been left in horses for many years. In two horses, infection and drainage recurred 5 months and 3 years, respectively, after all clinical signs of infection had resolved. In both cases, draining tracts were followed to the PMMA implants, and removal resolved the infection had resolved. In both cases, draining tracts were followed to the PMMA implants, and removal resolved the infection and drainage.

Regional perfusion should be considered in horses that develop postoperative orthopedic infections. This technique has the advantage of delivering high concentrations of antibiotics not only to the surgery site but also to the surrounding soft tissues and bones. This treatment has been used to successfully treat three horses with postoperative infection after fracture repair or joint arthrodesis.

Regional perfusion is being performed with increasing frequency because of its success in treating horses with postoperative infection after fracture repair or surgical arthrodesis. The antibiotics and the procedure used are the same as previously described for septic joints.

Both antibiotic-impregnated PMMA implants and regional limb perfusion can be used in the same horse. Regional limb perfusion gets antibiotics into the bone and vascularized tissues around the site of the infection, and antibiotic PMMA implants provide sustained release of antibiotics over several days or, in the case of some antibiotics, several months. Because infection of a fracture repair or joint arthrodesis has severe consequences, every effective treatment should be considered. Treatment decisions regarding selection of the method for delivering local antibiotics or whether both treatments are used are based on the clinical signs, the anatomic location of the infection, and the preference of the surgeon.

Traditional treatments of aggressive debridement and daily lavage of the surgery site have not been effective in eliminating orthopedic infection in horses. These techniques have been replaced with an approach of establishing effective drainage and increasing the concentration of antibiotics at the site of infection. Exposure of the implants should be avoided. More aggressive debridement, autogenous cancellous bone grafts, and large-volume lavage still may be indicated as part of the treatment in chronic cases. However, even when this approach is used, the soft tissues should be closed to provide coverage for PMMA implants that are placed after debridement. Procedures that expose implants should be avoided. Antibiotic-impregnated PMMA is an effective method of maximizing antibiotic concentrations locally at the site of infection. Regional limb perfusion is another effective treatment for maximizing antibiotic concentrations in the vascularized tissues around an orthopedic infection. Finding new and better carriers or techniques to maintain antibiotics at the site of infection will be important in the future treatment of orthopedic infection.

The treatment of orthopedic infection is expensive. The average days of hospitalization in 38 horses with an infected fracture or arthrodesis was 142 days (range, 16 to 804 days). These horses were receiving systemic antibiotics, daily bandaging, wound care, periodic cast changes, or a combination. All of these treatments contribute to the expense.

Prognosis

The prognosis for horses with orthopedic infections has been unfavorable; only 52.9% of 38 horses with an infected fracture or arthrodesis site survived to be released from the hospital. Horses were humanely destroyed as a result of infection. The infection rate during major orthopedic surgery in horses is 1.3% (out of 1352 horses). Data included both arthroscopy and arthrotomy procedures and spanned the time when osteochondral fragment removal changed from an arthrotomy to an arthroscopic procedure. Four horses developed infection after surgery during a 7-day period, the cause of which was traced to a malfunctioning gas sterilization unit. During this same 10-year period, the infection rate in horses with major fracture repairs or arthrodesis procedures was 6.9% (452 horses), including horses with open fractures. Ideally, the infection rate in both groups of horses should be lower; however, invasive surgery carries the risk of infection in all species. Estimates of the chance for infection in equine surgeries vary because of its success in treating horses with postoperative infection after fracture repair or joint arthrodesis. The antibiotics and the procedure used are the same as previously described for septic joints.

Both antibiotic-impregnated PMMA implants and regional limb perfusion can be used in the same horse. Regional limb perfusion gets antibiotics into the bone and vascularized tissues around the site of the infection, and antibiotic PMMA implants provide sustained release of antibiotics over several days or, in the case of some antibiotics, several months. Because infection of a fracture repair or joint arthrodesis has severe consequences, every effective treatment should be considered. Treatment decisions regarding selection of the method for delivering local antibiotics or whether both treatments are used are based on the clinical signs, the anatomic location of the infection, and the preference of the surgeon.

Traditional treatments of aggressive debridement and daily lavage of the surgery site have not been effective in
orthopedic surgery should be considered in preoperative discussions with horse owners regarding surgical risk. Principles of asepsis and prophylactic procedures discussed elsewhere in this book must be followed.

In the author’s experience, the incision can be an important source of postoperative infection. Protection of the incision from the environment (in the horse’s case, a stall with manure) is important. Some incisions are located over highly mobile areas, and a cast is necessary to allow the soft tissues to heal without excess tension. This is particularly true for incisions over the paternae. When these incisions are not immobilized, the skin sutures cut into the skin and cause local infection, or the incision dehiscs. Horses develop infection when the skin sutures have been either left in too long or incompletely removed (the knot is cut off, leaving a loop of suture material deep in the skin incision). Sutures removed between 10 and 14 days are almost never a problem. Skin sutures left in for longer than 14 days may be the cause of infection and drainage along the suture line. The superficial infection beneath the skin can easily penetrate deeper tissues, especially if the skin incision is superimposed over an incision that penetrates deeper tissues. Even small arthroscopy incisions can develop infection that penetrates down the arthroscope or instrumental portal to the joint. When part or all of the suture is left in these sites, the horse may, in some cases 6 or 7 weeks after surgery, develop a septic joint.

Preventative antibiotic treatment in the horse has progressed beyond preoperative administration of systemic antibiotics. In horses with open fractures or contaminated joints undergoing internal fixation procedures, antibiotic-impregnated PMMA can be placed along the plates at the time of surgery to decrease the chance of infection. Similarly, regional limb perfusion can be performed at the time of surgical fixation, with the same rationale. When to use these procedures or choosing between the two is based on the judgment and the clinical experience of the surgeon.

CHAPTER 89
Angular Limb Deformities
Jörg A. Auer

The surgical techniques used for the management of angular limb deformities (ALD) in foals are well established. However, when to use these techniques remains controversial. At one time, most foals showing some degree of angular deviation were surgically corrected, but a more conservative approach has been advocated recently. The following quote best represents the current thinking on managing ALD: “Foals should be expected to be born crooked and to correct with time. It is equally as wrong to disturb this process, as it is not to correct a variation from it.” Looking at ALD from this point of view allows objective criteria to be developed to manage them.

DEFINITION
Animals with ALD present with either a valgus deformity (lateral deviation of the limb distal to the location of the deformity) or a varus deformity (medial deviation of the limb distal to the location of the problem) (Fig. 89-1). Either type of deviation is usually associated with a certain degree of axial rotation. In foals with valgus deformity, this is displayed as an outward rotation (splay foot), and in cases of varus deformity, as a medial rotation of the feet (pigeon toes). In most cases, these deformities are initially merely postural, through a rotation of the limb axis toward either the outside or the inside, respectively. With time, however, the bone adapts to abnormal loading, according to Wolff’s law, and differential metaphyseal growth results in the development of a permanent rotational deformity.

ANATOMY

CHAPTER 89

Angular Limb Deformities

Jörg A. Auer

The surgical techniques used for the management of angular limb deformities (ALD) in foals are well established.1-11 However, when to use these techniques remains controversial. At one time, most foals showing some degree of angular deviation were surgically corrected, but a more conservative approach has been advocated recently. The following quote best represents the current thinking on managing ALD: "Foals should be expected to be born crooked and to correct with time. It is equally as wrong to disturb this process, as it is not to correct a variation from it."12 Looking at ALD from this point of view allows objective criteria to be developed to manage them.

DEFINITION

Animals with ALD present with either a valgus deformity (lateral deviation of the limb distal to the location of the deformity) or a varus deformity (medial deviation of the limb distal to the location of the problem) (Fig. 89-1). Either type of deviation is usually associated with a certain degree of axial rotation. In foals with valgus deformity, this is displayed as an outward rotation (splay foot), and in cases of varus deformity, as a medial rotation of the feet (pigeon toes). In most cases, these deformities are initially merely postural, through a rotation of the limb axis toward either the outside or the inside, respectively. With time, however, the bone adapts to abnormal loading, according to Wolff's law,13 and differential metaphyseal growth results in the development of a permanent rotational deformity.7

ANATOMY

Maturation of the skeleton from the primordial or precursor cartilage to bone is a very complicated process and occurs mainly during the later stages of gestation. Radiographs
taken of the carpal and tarsal regions of aborted fetuses at 230 days of gestation reveal only partial ossification of the diaphyses and metaphyses of the long bones as well as of the calcaneus.\textsuperscript{11} Other bones are not ossified at all at that time. For instance, intra-articular injections of contrast medium provide outlines of the bone templates in their normal shapes, although they consist of precursor cartilage only. Ossification of these structures begins in the center and expands spherically in all directions to the periphery.\textsuperscript{11,14} At about 260 days of gestation, ossification centers are noticed in the distal radial epiphysis, distal tibial epiphysis, talus, and accessory carpal bone. Later, ossification centers in the intermediate, radial, and third carpal bones, and the central, third, and fourth tarsal bones develop. At around 290 days, the proximal epiphyses of the third metacarpus/third metatarsus (MCIII/MTIII) appear, and they unite shortly thereafter with the metaphyses of these bones (Fig. 89-2). At about 300 days of gestation, all bones of the carpus and tarsus are visible radiographically. The ulnar styloid process, which is the last ossification center to appear, is still not seen at this time. During the remaining days of gestation, ossification progresses toward the periphery, and the bones acquire their final shape. At birth, the edges of these bones are still somewhat rounded, but the “radiographic joint spaces” are within normal limits (Fig. 89-3). These spaces consist of two layers of cartilage in addition to the actual joint space.\textsuperscript{5,15,16}

The vast majority of longitudinal growth in the long bones occurs at the level of the physis. Some growth is attributed to the epiphysis, growing both toward the articular cartilage and the physis. However, the vast majority of growth occurs in the metaphyseal region of the physis. The exact mechanisms responsible for this bone growth are not completely understood, but strides toward solving this mystery are being made with the help of molecular biology techniques. In mice, it was found that a feedback loop exists in the growth plate centered on the following molecules: parathyroid hormone–related protein (PTHrP), PTH/PTHrP receptors (PTHrPR) and Indian hedgehog (Ihh).\textsuperscript{17} The feedback loop is regulated via the periosteum/perichondrium.

Note the ununited proximal epiphysis of MTIII (arrow).

**Figure 89-3.** Normal ossification of the carpal and tarsal regions at the time of birth.\textsuperscript{A} Dorsopalmar radiograph of the carpal region. All the bones are ossified adequately, and the ulnar styloid process (a) is visible. The rough surface at the medial distal metaphysis of the radius (b) represents active endochondral ossification and is normal at that age.\textsuperscript{B} Lateromedial radiograph of the tarsal region showing adequate ossification of the central and third tarsal bones (arrows). It is important that the ossification process proceed to the level of the proximal aspect of MTIII. These two radiographic views are the most relevant to evaluate ossification at the time of birth.
through the signaling molecules Patched1 (Ptc1), Gli, and Smoothend (Smo). If Ihh secretion is increased, PTHrP molecules are upregulated and inhibit differentiation of proliferating chondrocytes into hypertrophic chondrocytes, thus promoting longitudinal growth. Since Ihh and PTHrP are not expressed in the same vicinity and molecule diffusion through the extracellular matrix is limited, intermediates, such as Ptc1, transforming growth factor (TGF)-β, bone morphogenic proteins (BMPs), and fibroblast growth factor (FGF) that are located in the perichondrium participate in this regulatory process. Once these mechanisms are understood in the horse, an explanation for the disproportionate long bone growth across a physis may become clear and specific molecular therapy may be developed.

The following is clear. Ideally, bone growth should occur evenly across the entire physis; immediately after birth, growth is most active; and each physeal region has an approximate time span during which new bone occurs. Closure of the physes of the different long bones occurs at predictable time points. Therefore, if manipulations to correct growth are to be effective, the closure time of the physes have to be considered.

ETIOLOGY

A variety of etiologies are responsible for the development of ALD, and can be grouped into two main categories (Fig. 89-4): perinatal factors, which include conditions that are present either during the later phases of gestation or in the immediate perinatal period, and developmental factors, which influence limb axes at a later stage.

ALD may originate at different locations of the appendicular skeleton: within the cuboidal bones of the carpus or tarsus; in the epiphyseal region of the long bones (epiphyses, physes, and metaphyses), and occasionally in diaphyses of the long bones. Most frequently, the deviation develops through disproportionate growth at the level of the metaphyseal growth plates. Physeal trauma, such as Salter-Harris type V or VI fractures, can cause local retardation of growth at the medial or lateral aspect of the bone and result in the development of ALD. Compensatory ALD can occur in remote sites in the affected limb because of disproportionate loading of a growth plate distally. Such compensatory deviations may straighten the limb axis, but when the foal ambulates, the joint involved rotates, because the joint is not oriented at a right angle to the long axis of the limb.

Perinatal Factors

Incomplete Ossification

After a normal gestation period, a foal should be born with adequate ossification of the carpal and tarsal bones (see Fig. 89-3). A variety of events affecting the mare, including placentitis during pregnancy, severe metabolic disease over a prolonged period, heavy parasite infestation, and colic, may jeopardize the intrauterine environment of the foal and result in incomplete ossification at the time of birth. Premature birth is usually associated with the same problem. Because the placenta of a mare does not provide as

---

**Figure 89-4.** Interrelationship of perinatal and developmental factors and pathways and how they may contribute to the development of an angular limb deformity.
intricate a blood exchange between the fetus and the mare as it does in humans and dogs, normal intrauterine development of more than one fetus at the same time is not possible. Twin foals always exhibit incomplete ossification at birth. These immature foals do not mature properly and have a poor prognosis as athletes. Therefore, abortion of one of the twins during the early embryonic stages is standard.

Because most foals are born with a certain degree of angular limb deformity, they initially load their joints unevenly. The uneven pressure on the relatively thick layer of articular and precursor cartilage may deform that soft structure, especially in a dysmature foal. Incomplete ossification per se does not represent an ALD, but the uneven loading of the dysmature skeleton leads to it. Once ossification reaches the periphery, the abnormal shape of the bone results in a permanent ALD. Additionally, the force of digital extension is applied laterally in the carpal and tarsal regions and may impede longitudinal growth in these areas to a certain extent. In severely dysmature foals, osteochondral fractures may occur, which render the foal permanently lame because of osteoarthritis9 (Fig. 89-5). This is especially true in the rear limb, where weight-bearing forces must change direction in the tarsal region from a cranioproximal-caudodistal direction to a vertical one. The most affected region is the dorsal aspect of the small tarsal bones. If these bones are incompletely ossified, loading causes thinning of the soft precursor cartilage. This may be followed by pathologic fracture and dislocation of a dorsal fragment.6,9 This problem results in a partial collapse of the dorsal aspect of the tarsus and tilting of the proximal limb in a cranial direction (Fig. 89-6). Affected foals do not trot but rather “bunny hop” with their rear limbs. In chronic cases, a secondary flexural deformity of the forelimbs may result because of chronic overload.

If collapse of the cartilage template of cuboidal bones in dysmature foals is left untreated, the deformations worsen and eventually become impossible to correct. Therefore, early intervention and aggressive treatment are necessary to ensure normal development.

**Laxity of Periarticular Structures**

Some foals are born with severe ALDs in several regions, allowing oscillation between valgus and varus deviations depending on limb position during weightbearing. Rotational deformities of various degrees also are encountered during the first few days of birth (Fig. 89-7). These foals probably suffer from laxity of the periarticular supporting structures or from soft tissue trauma, both of which result in unstable joints. In most cases, several joints are involved at the same time. These deformities lead to abnormal loading of the articular surfaces and may, in the presence of incompletely ossified cuboidal bones, induce a severe ALD. It is unknown exactly how these problems develop. In some cases, the aberrant development of the long bones relative to the soft tissue structures may be caused by a hormonal imbalance or by intrauterine positioning.20

**Developmental Factors**

**Unbalanced Nutrition**

The common practice of “crib feeding” often leads to excessive grain intake. It is important that the nutrition be balanced, especially with regard to trace minerals.21 If the

![Figure 89-5](image-url). A, A 6-week-old foal with a marked carpal valgus deformity in the left limb. There is swelling (arrow) and the animal is lame. B, Postmortem picture of the articular surface of the third carpal bone, showing an osteochondral fracture (arrows). There is also marked discoloration of the synovial membrane caused by intra-articular hemorrhage.
Figure 89-6. A, The hind limbs of a 1-month-old foal with a marked dorsal angulation at the level of the tarsus (arrow). The foal showed the typical gait of a foal with collapsed third tarsal bones: it trotted with the forelimbs and "bunny-hopped" with the hindlimbs. B, Lateromedial radiograph showing the collapsed third tarsal bone, which is displaced dorsally.

Figure 89-7. A, Photograph of a 1-week-old foal with a marked valgus deformity of the right tarsus (white arrow) and a varus deformity of the left tarsal region (black arrow). The degree of ossification was normal. B, After 2 weeks of light hand-walking and no treatment, the deviations had corrected.
diet is not balanced, developmental orthopedic disease may occur and jeopardize future athletic potential. Intake of trace minerals is further compromised by the exhaustion of grasslands and a lack of appropriate fertilization. A soil analysis of the local pasture may not be relevant, because forage (hay) is usually brought in from a distant source. Problems associated with unbalanced nutrition include flexural deformities, osteochondrosis, and ALD, the latter being represented mainly by disproportionate growth at the level of the physes. Severe generalized osteochondrosis because of zinc toxicity or copper deficiency may cause ALD. On farms with a high occurrence of ALD, feeding practices should be evaluated through a complete feed and water analysis. If abnormalities are encountered, they should be corrected at once.

**Excessive Exercise and Trauma**

Excessive exercise and trauma cause ALD. This trauma induces microfractures in and actual crushing of the proliferative zone at the base of the physes, altering cell proliferation and maturation. In severe cases, it leads early local closure. This type of injury has been classified as a Salter-Harris type V fracture. Additionally, epiphyseal fractures caused by external trauma such as kicks from another mare may cause ALD. Most physeal fractures heal with residual ALD because it is almost impossible to maintain viability of the entire physeal plate.

**DIAGNOSIS**

Diagnosis is based on inspection, manipulation, and diagnostic imaging techniques. The foal is observed from several angles, most importantly from the front and back. To evaluate the limb, the clinician should be positioned perpendicular to a frontal plane through the examined limb. Splay-footed foals, with or without ALD, are therefore evaluated from a cranialateral position, allowing observation for proper alignment of the toe and carpus or tarsus, respectively (Fig. 89-8, A). It is very important that the toe point in the same direction as the carpus. Most newly born foals are weak, thin-chested, and, in relation to their size, long-legged. To provide some support to the forelimbs, which are connected to the chest only by seven muscles, the proximal ulna is positioned on the side of the chest. This results in an outward rotation of the entire limb and a toed-out posture. With increasing strength and age, the chest fills out and the connecting muscles become stronger, leading to an inward rotation of the limb and correction of the toed-out posture. Should, however, the carpus or tarsus point outward but the

![Figure 89-8. A, A valgus deformity of the carpal region is evaluated perpendicular to the frontal plane of the outward-rotated carpus. If the toe points in the same direction, the entire limb is rotated out and surgery can possibly be postponed. B, If the toes point forward and the carpus outward, surgical intervention is indicated to prevent the development of a varus deformity in the fetlock region.](image)
toes point straight forward (see Fig. 89-8, B), a varus deformity of the distal limb is present, which may go unnoticed for a few months. Once the limb rotates into a normal position, the feet attain a toed-in posture. Unfortunately, the distal MCIII/MTIII experiences longitudinal growth only for 3 to 4 months, after which the physis closes. Frequently, this is when the problem is noticed.

Palpation and manipulation of the limb help differentiate between perinatal and developmental deformities. If application of manual pressure to the medial aspect of the carpal region straightens out a valgus deformity (Fig. 89-9), the cause of the deformity is either incomplete ossification or flaccidity of the periarticular supporting structures. If the limb cannot be straightened with manipulation, changes of the osseous structures of the region are involved.

Observation of the foal as it walks toward and away from the clinician also provides valuable clues. If the joints are aligned parallel to the ground, all the joint movements occur in the same planes and no outward or inward rotation of a joint is noticed. However pigeon-toed foals frequently rotate their metacarpophalangeal/metatarsophalangeal (MCP/MTP) joints outward while advancing the limb. This is caused by the joints not being oriented parallel to the ground.

The only diagnostic aid that allows exact determination of the location and degree of the deformity is radiography. It is important to use long, narrow cassettes for the radiographs and to include as much of the bones proximal and distal to the deformity as possible. The dorsopalmar/dorsoplantar views are most important, except in the tarsus, where the lateromedial view is preferred. The radiographs should be taken at a right angle to the frontal plane of the limb (the sagittal plane of the tarsus). The bones constituting the distal MCIII/MTIII and phalangeal region should be aligned in one plane for the radiographs, allowing interpretation of the articular orientation and differentiation of deformities.

The need for early diagnosis cannot be overemphasized, especially in foals with incomplete ossification. The soft precursor cartilage is deformed through the uneven axial loads and, combined with the rapid progression of endochondral ossification, may result in a permanent deformity within 2 weeks after birth.

Compound and noncorrectable deformities present an added challenge. It is sometimes important to accept a compensatory deformity, if it aids the overall athletic soundness of the animal. A foal with a varus deformity in the metacarpophalangeal region would profit from a slight valgus deformity in the carpal region to balance the horse’s weight-bearing axis over the foot. This necessitates the visual evaluation of the entire limb at the time of the diagnosis, and caution in using radiographs as the sole diagnostic aid.

TREATMENT
Two recent studies conducted in Thoroughbred horses have significantly changed the philosophy of the management of ALDs. One study documented conformational changes with age. The changes occurring from weaning age to 3 years in a population of racing Thoroughbreds were determined by recording specific body measurements. There was a strong relationship between long bone lengths and wither height in all age groups, supporting the theory that horses grow proportionally. Longitudinal bone growth in the distal limb increased only 5% to 7% from weaning age to 3 years and was presumably completed prior to the yearling year. This study provided objective information regarding conformation and skeletal growth in the Thoroughbred, which can be utilized for selection and recognition of significant conformational abnormalities.

The other study investigated the relationship of conformation to injury. It found that offset carpi (offset ratio) contributed to MCP joint problems. Long pasterns increased the odds of a fracture in the front limb. A certain degree of carpal valgus deformity exhibited a protective mechanism, since the odds for a carpal fracture and carpal effusion decreased with an increase in the carpal angle.

Based on these studies, the goals of effective management of ALD have changed. Severe deformities that do not correct on their own (see Fig. 89-5) need to be distinguished from deviations that are a variation of the normal. The art of management of ALD involves deciding which conditions require immediate aggressive management and which can tolerate a wait-and-see approach.

The following treatment methods are divided into nonsurgical and surgical procedures, according to the appearance and severity of the problem.

Nonsurgical Techniques
Stall Rest
Stall rest is an effective treatment in newborn foals with certain types of ALD. The following problems can be treated with stall rest:

Foals with incomplete ossification and straight limbs at the time of birth. Under no circumstances should these

Figure 89-9. Manual pressure to the medial aspect of the carpal region of a foal suffering from bilateral valgus deformity corrects the deformity temporarily, indicating that conservative treatment is possible. Counter-pressure is applied to the fetlock region of the same limb.
animals be turned out in a field. Exercise on the weakened, partially ossified carpal and tarsal bones may result in abnormal ossification of the bones with subsequent development of osteoarthritis. Stall rest should be maintained for a maximum of 1 month. While the animal is on stall rest, radiographs should be repeated at 2-week intervals to evaluate the progress of ossification.

Foals with adequate ossification and ALD because of disproportionate growth at the level of the physis (greater than 10 degrees) and foals with diaphyseal deformities. Stall rest may be continued for 4 to 6 weeks. If correction is not achieved during that time, surgical treatment should be attempted.

Foals with laxity of the periarticular supporting structures and a normal degree of ossification. Such animals should be exercised daily for 10 to 20 minutes through walking the mare, to stimulate muscle work and strengthening of the involved soft tissue structures. Three to 5 minutes of swimming daily is the best exercise if facilities are available (see Chapter 90). Growth of the foal usually resolves the deformity.

Predicting whether the problem will resolve with stall rest alone is not possible, and valuable time can be lost by waiting too long. This is the main reason for not prolonging stall rest treatment beyond 4 to 6 weeks. It is important to critically observe the foal continually during the stall rest period.

Splints and Casts

Foals with incomplete ossification of the carpal and tarsal bones may be treated effectively with splints or casts (Fig. 89-10, A). The purpose of these devices is to maintain the limb in proper alignment and to allow the inadequately ossified cartilage template to ossify sufficiently and facilitate weightbearing without detrimental consequences. It is of paramount importance that the cast or splint end at the fetlock. If the foot is incorporated in the splint, the musculotendinous flexor and extensor units weaken, resulting in a dropped fetlock and osteopenia. In most cases, this problem is of a temporary nature, but it should be prevented because it may lead to additional orthopedic problems. The limb

![Figure 89-10](image-url)
should be well padded before splint or cast application. The splint is changed every 3 to 4 days, and dry padding is placed next to the limb. Casts should be changed between 10 and 14 days after application. Leaving the cast on for too long results in skin damage because of the rapid growth of young foals. The radiographic evaluation is repeated at 2-week intervals and the change in degree of ossification is determined.

Casts and splints should be maintained as long as incomplete ossification is present. Depending on the degree of ossification at the time of birth, this may take 2 to 4 weeks (see Fig. 89-10, B and C). In twin foals, it may be continued for up to 2 months of age.

While the limb is under a cast or splint, the flexor carpi ulnaris and the ulnaris lateralis muscles are immobilized and become flaccid. This results in a temporary calf-kneed conformation immediately after the cast is removed (see Chapter 90). Additionally, pressure necrosis of the skin over the accessory carpal bone may develop. However, with time, these defects correct as strength returns to the muscles. Daily swim therapy is beneficial and helps in rapidly overcoming this condition. It is important to keep the limb bandaged for an additional 4 to 5 days after the cast or splints are removed.

If radiographs demonstrate that the deformity is located within the distal radius or tibia and is not caused by laxity of the periarticular supporting structures or incomplete ossification, splints and casts are ineffective and, in fact, contraindicated. Application of such devices almost invariably results in pressure sores without correction of the deformity.

Aside from somewhat labor-intensive management with the help of polyvinylchloride (PVC) half-shell splints, custom-fitted snap-on splints made of padded fiberglass (Endurasplint 2, Carapace Inc., New Tazewell, Tenn) can be used. These splints have enough strength for foals younger than 6 weeks of age. The foal is sedated and placed in lateral recumbency, and a rectal sleeve is placed over the limb to protect it from contact with water and polyurethane resin. The splint material is immersed in warm water (21°C to 23°C [69.8°F to 73.4°F]) until it is soft and pliable. Excess water is squeezed out and the splint is swiftly applied to the limb with the felt positioned against the skin and covering half of the circumference of the limb. It is secured to the limb with gauze and allowed to dry, with care taken not to flex the limb during the setting time. The splint is removed and allowed to set for 5 to 7 minutes before reapplying it to the limb. Because the splint is padded and molded to the contour of the limb, it is easy to place, and only a single roll of self-adhesive elastic is needed to secure it, making it convenient for daily use. In a hospital setting, it is recommended that the splint be left on for 12 hours at a time to prevent pressure sores; it should be applied at night while the foal is less active.

Special custom-fitted hinged braces, which allow the foal to move the carpal and tarsal regions while maintaining correct axial alignment, have been introduced to the market (Farley brace [Indialantic, Fla], Redden brace [International Equine Podiatry Center, Versailles, Ky]). Foals with incomplete ossification or laxity of the periarticular supporting structures can be successfully treated with these devices. Because these braces allow movement of the joints, this type of treatment is theoretically preferred over stiff splints or casts. However, this is the only application of such braces in foals with ALD.

**Hoof Manipulation**

Corrective hoof trimming is a frequent conservative treatment of ALD. In valgus deformities, the outside half of the hoof wall is slightly shortened. This causes the inside half of the foot to contact the ground first, and during the process of placing weight on the entire foot, it rotates medially. This type of hoof trimming is carried out with a rasp in young foals. In contrast, for varus deformities and pigeon-toed conformation, the inside wall is slightly lowered. In young foals, this type of treatment may be beneficial as an **adjunct** therapy to a surgical technique and should be maintained for only a few weeks to months because of the danger of the development of an abnormal hoof shape and of interphalangeal joint osteoarthritis.

The application of foot plates or shoes with an extension to the inside or outside may assist in correcting the deformity. Additionally, these devices prevent excessive wear-down at certain areas of the foot. For valgus deformities, extensions are placed on the medial side of the foot, and for varus deformities, on the lateral side. It is important to fill the extensions placed on the medial aspect of the hoof with acrylic to prevent stepping onto the plate with the other foot.

Corrective hoof trimming should **not** be used as the sole treatment for significant ALD in older foals. By forcing the foot into an uncomfortable, abnormal position, torsional and stress forces are created that cause early degenerative changes of cartilage and periarticular structures. Therefore, it is better to opt for surgical procedures at the location of the deformity than to try to bring about correction through altering the loading conditions of the entire limb up to the location of the deformity.

**Surgical Techniques**

The surgical techniques for correction of ALD are reviewed for the carpal region, because this is the area where ALD is diagnosed most frequently. As the various techniques are discussed, consideration is given to the other anatomic regions where these surgical procedures may be used.

**Growth Acceleration**

Since its introduction into equine surgery, periosteal transection and elevation (stripping) has gained universal acceptance. Periosteal transection is performed on the concave aspect of the limb (e.g., in an animal with a valgus deformity in the carpal region, on the lateral side). A 3-cm vertical skin incision is made between the common and lateral digital extensor tendons, starting from a point 4 to 5 cm proximal to the distal physis of the radius and continuing in a proximal direction (Fig. 89-11, A). The incision is carried down to the periosteum. With a curved hemostatic forceps, the subcutaneous tissues and tendons are separated from the periosteum parallel to the physis and perpendicular to the skin incision at its distal border. The forceps is abducted, with its slightly spread tips pressing onto the bone. Under this protection, a curved scalpel blade...
(no. 12) is inserted cranially between the tips of the hemostatic forceps. Using moderate pressure, the scalpel blade is pulled back toward the level of the skin incision, transecting periosteum. Once the blade has reached the lateral aspect of the bone, the incision is stopped. The same procedures are repeated on the caudal aspect of the distal radius. The hemostat is first advanced to separate the lateral digital extensor tendon from the rudimentary ulna and then is redirected to a frontal plane to reach the caudal aspect of the distal radius. The scalpel blade is inserted under the protection of the forceps, and the periosteum, including the rudimentary ulna, is transected as described earlier. The cranial and caudal incisions are connected. Because this transection severs the rete carpi volaris, marked bleeding occurs. The periosteum is then incised parallel to the skin incision in a proximal direction over a length of 2 cm, starting at the horizontal periosteal incision, to create an inverted T. The periosteal elevator is advanced at a 45-degree angle to the periosteal incisions underneath the periosteum to elevate two triangular flaps (see Fig. 89-11, B). Once elevated, the periosteum is gently laid back onto the bone to prevent the ends from curling, which could result in new

**Figure 89-11.** Locations at which growth acceleration may be carried out. **A,** Anatomic relationship of the landmarks for the surgical approach at the distal carpus (common digital extensor tendon cranially, lateral digital extensor tendon and rudimentary ulna caudally, and the distal radial physis distally). **B,** The periosteal transection is completed on the caudal aspect. The rudimentary ulna is transected, and the caudal periosteal flap is being elevated. **C,** Location of growth acceleration at the distal MCIII/MTIII and proximal phalanx. The procedures are performed, and the flaps are elevated. **D,** Anatomic relationship of the landmarks for the surgical approach at the distal tibia. The periosteal transection procedure was carried out through an approach cranial to the lateral digital extensor tendon. The vertical periosteal incision caudal to the lateral digital extensor tendon is an alternate site (dotted line). **E,** Location of the procedure carried out over the total length of the MCIII/MTIII. The procedure was performed and the two periosteal (barn-door) flaps were elevated.
bone formation. The subcutaneous tissues are closed in a simple-continuous suture pattern, using 2-0 absorbable suture material, followed by a simple-continuous intradermal suture line. This results in an acceptable cosmetic appearance of the surgical site.

In about 20% of all cases, the rudimentary ulna is ossified and therefore has to be removed with rongeurs. It is important that the rudimentary ulna be transected, because it can act as a tethering mechanism and slow down growth at the concave aspect of the radius.

Postoperatively, a bandage, consisting of a nonadherent dressing (Telfa, Kendall Company, Boston, Mass) and unfolded 4×4 gauze sponges, covered by an adhesive elastic bandage (Elasticon, Johnson & Johnson Products Inc, New Brunswick, NJ), is applied. The elastic tape is attached directly to the skin for a width of 2 cm proximal and distal to the gauze sponges. The bandage is replaced 3 days postoperatively. The second bandage may stay in place for an additional week before it is removed. No skin sutures need to be removed because the sutures are below the skin surface (intradermally). It is advisable to keep the animal in a stall for 2 to 3 weeks and to allow minimal exercise during that time.

Postoperatively, the outside of the feet (in a valgus deformity) are rasped slightly every 2 weeks to assist in correction of the outward rotation of the feet and straightening of the limbs.

The surgery can be carried out in a foal as young as 2 weeks of age. The earlier the surgery is performed, the faster the correction occurs (Fig. 89-12). However, opting for surgical intervention at such an early age may include foals in which the deformity would have corrected spontaneously if the animal was allowed stall rest. Therefore, foals should be selected for this surgery after 4 weeks of age, unless the ALD is severe (greater than 10 degrees).

The landmarks for periosteal transection at the distal MCIII/MTIII are the distal-most aspect of the metaphysis of MCIII/MTIII or MCIV/MTIV and, depending on the location of the concavity of the deformed bone, the medial or lateral aspect of the bone (see Fig. 89-11, C). Care should be taken not to enter the palmar or plantar outpouching of the MCP/MTP joint. These surgical interventions must be performed prior to 3 months of age, because after that there is only limited growth at the distal physis of MCIII/MTIII.31 The periosteum at the surgical site of MCIII/MTIII is markedly thinner than that of the distal radius or tibia.9

Surgery at the proximal phalanx should be carried out at the level where the extensor branch of the suspensory ligament curves over the lateral or medial aspect of the bone32 (see Fig. 89-11, C). On this bone, the periosteal incisions are performed in a T-shaped configuration, with the horizontal incision about 1 cm distal to the physis and the vertical incision in a distal direction. At the palmar or plantar aspect of the horizontal incision, some attachments of the oblique

distal sesamoidean ligaments will be transected. This appears to present no serious consequences but can result in minor new bone formation that resolves with time.

The surgical approach for the distal tibia is either cranial or caudal to the lateral digital extensor tendon (see Fig. 89-11, D). The rest of the procedure is carried out in a fashion analogous to that described for the distal radius. It is interesting to note that the periosteum in that area is thicker than that at any other surgical site discussed earlier.

“Bench knees” are a frequently encountered conformational defect that may continue to develop after 1 year of age. These conformational defects are the result of two opposing ALDs—a valgus deformity at the distal radius and a varus deformity of the proximal third of MCIII (Fig. 89-13). The limb has a straight appearance in the presence of bench-kneed (off-set) conformation. If this conformational defect is diagnosed within the first 2 months of life, periosteal stripping can be carried out at the lateral aspect of the distal radius and over the entire medial aspect of MCIII, starting 2 cm proximal to the distal physis and up to 3 cm below the carpometacarpal joint (Fig. 89-14). A horizontal incision is carried out at each end of the longitudinal incision, producing an L-shaped incision in the periosteum (see Fig. 89-11, E). The two flaps are elevated, and the subcutaneous tissue and skin are closed as previously described. Periosteal stripping over the total length of MCIII/MTIII is also effective in correcting diaphyseal or metaphyseal deformities of that bone in foals younger than 2 months (Fig. 89-15).

Periosteal transection has its effect for approximately 2 months, which corresponds to the time needed to fill in the defect between the transected ends of the periosteum. A prolonged effect is achieved through surgical excision of the elevated triangular flaps. Periosteal transection can be repeated if complete correction is not achieved. Overcorrection of the deformity does not occur.

It has been shown that periosteal transection carried out when the ALD is located within the carpus also corrects malformation of these bones to some degree. Nevertheless, such problems should be recognized earlier and the incomplete ossification treated during the immediate postnatal period, as described previously. However, surgery accelerates correction even in these cases, allowing the foal to participate in exercise at an earlier age while preventing the development of additional deformities further distally (e.g., digit, hoof).

Periosteal transection and elevation are routinely carried out on an outpatient basis, with the mare and foal returning home immediately after recovery from surgery. The most critical location for early diagnosis and surgery is the distal MCIII/MTIII, because longitudinal growth of MCIII/MTIII occurs mainly during the first 3 months after birth. Later on, growth occurs at a very slow pace, and delaying surgery leads to incomplete correction. Additionally, the prolonged...
abnormal loading of the metacarpophalangeal joints leads to the development of compensatory deformities in the proximal phalanx. Thus, the limb may appear to be straight, but when the foal walks, an outward rotation is noted. This is caused by the orientation of the articular surfaces, which are not parallel to the ground (Fig. 89-16).

During the first weeks of life, affected foals show an outward rotation of the carpal region while their feet point straightforward (see Fig. 89-8, A). At that point, an actual varus deformity is hard to detect, especially for an inexperienced clinician. With time, the deformity is aggravated, making diagnosis easy but surgery difficult.

Recently, the effectiveness of hemi-circumferential periosteal transection and elevation in treating ALD was questioned. In a controlled study, temporary transphyseal bridging was performed on the lateral aspect of the distal radius to induce a carpal valgus ALD of 15 degrees in normal young foals. At the time of implant removal, the foals were divided into two groups. One group was subjected to an immediate hemi-circumferential periosteal transection and elevation on the same lateral aspect of the distal radius, whereas the other group underwent a sham surgical procedure at the same site to mimic the hemi-circumferential periosteal transection and elevation procedure. In both groups, the deformity corrected, leading to the erroneous conclusion that periosteal transection and elevation was ineffective. Three facts might explain the results: (1) the deformity was induced artificially through manipulation of the physis, (2) a clinical case with a carpal valgus deformity of 15 degrees does not correct without surgery, and (3) physeal growth is influenced by mechanical load, which in turn triggers signal molecules in a feedback loop between the cells of the different cartilage zones and the perichondrium or periosteum of the limb involved. This regulatory mechanism of signaling molecules was triggered at the time of initial surgery, when the periosteum was disturbed, and it was accentuated by the second surgery, performed to remove the implants. Periosteal transection could not be expected to further trigger this cascade. Therefore, no difference between groups could be expected.

Preliminary data of ongoing research to elucidate the effects of hemi-circumferential transection of the periosteum and local periosteal stripping revealed that local signaling processes occurring at the physeal level involve the feedback loop of PTHrP, PTHrPR, and Ihh and determine the normal growth mechanism and its acceleration. Additional work is needed, but there is a good chance that the phenomenon of growth acceleration through hemi-circumferential transection of the periosteum and local periosteal stripping can be explained through these processes and thus lay to rest the discussion on effectiveness once and for all.
Growth Retardation

Growth retardation is performed either in young foals (less than 3 months of age) with severe ALD or in foals with significant ALD in a bone after the rapid growth phase is over (MCIII/MTIII and proximal phalanx after 2 months, tibia after 4 months, radius after 6 months). The techniques described for growth retardation use the same principle. Implants, applied on the convex aspect of the bone, bridge the physis temporarily, allowing the shorter aspect of the bone to continue to grow, eventually correcting the deformity.

Stapling was the first technique of growth retardation described in the foal. The surgery is performed in some clinics with favorable results but is not discussed here because it has fallen into disfavor. Complications include implant and correction failures.

Screws and cerclage wires are the most frequently applied implants. Implants are inserted through two stab incisions, one in the center of the epiphysis and the other proximal to the physis (Fig. 89-17, A). The soft tissues between these incisions are elevated with a hemostat (see Fig. 89-17, B). A 4.5-mm cortex screw is inserted through each incision but not completely tightened (see Fig. 89-17, C). A wire loop is inserted through the proximal incision and hooked over the distal screw head (see Fig. 89-17, D). The two wire ends are twisted together and tightened over the proximal screw head (see Fig. 89-17, E). Twisting the wire ends over the proximal screw rather than the distal screw results in less irritation of the surrounding soft tissues and produces a better cosmetic result.

The screws are tightened completely, which increases wire tension as the wires ride up on the shoulder of the screw heads. The stab incisions are then closed with two simple-interrupted skin sutures, and the area is protected with a light bandage for approximately 10 days. Sutures can be removed by the referring veterinarian. In foals with minor ALDs and laterally rotated forelimbs, surgery may be delayed for some time. However, foals with carpal valgus deformity and feet pointing straight forward should be treated immediately to prevent a toed-in conformation from developing. A second wire applied over the two screw heads strengthens the configuration and reduces the risk of wire failure and subsequent loss of growth retardation. The two stab incisions improve the overall cosmetic result considerably, compared with the large incision initially used.

Very recently, implantation of a transphyseal screw has been described as a method of retarding growth (Fig. 89-18). The screws are inserted fully threaded and between the physis to arrest growth. They can be used in the physes of the distal MCIII/MTIII, distal radius, or distal tibia. The screws are removed when the desired conformation is reached. The advantages are ease of insertion and the improved cosmesis when a single screw is used. In the normal physis, the screw hole heals without affecting the foal’s growth at the physis.
A small, 2.7-mm bone plate can be used to correct ALD in older foals. The last hole on each side of the plate is enlarged to accept a 3.5-mm cortex screw. The plate can be implanted through stab incisions \(^9,10\) (Fig. 89-19). This technique provides an excellent cosmetic appearance of the limb. The surgical approach consists of either a slightly curved incision centered over the physis or a stab incision on either side of the physis. The distal stab incision is carried out parallel to the fibers of the collateral ligament. A 2.5-mm hole is drilled and tapped into the physis parallel to the joint surface, which is readily palpable. A 2.7-mm bone plate of adequate length is manually contoured to the shape of the bone and slid through the proximal stab incision distally, where the 3.5-mm screw of about 26 mm in length is inserted through the distal hole of the plate.

An additional hole of the same diameter is drilled about 1 mm proximal to the last hole of the plate into the radial metaphysis. The hole is tapped, and the second screw is inserted into the hole. Both screws are tightened alternately until they are completely inserted into the bone (see Fig. 89-19). It is important that the distal screw be tightened completely to prevent it from protruding into the collateral ligament. The skin incisions are closed with simple-interrupted sutures. Radiographic evaluations should be carried out at monthly intervals to determine the correct time of implant removal and to prevent overcorrection of the deformity.

Growth retardation procedures also may be performed in the distal MCIII/MTIII, the proximal phalanx, and the distal tibia \(^5,9,10\). It is important to evaluate the anatomic
situation at each location. This is especially important for the distal tibia, where the epiphysis has an undulating configuration and the distal screw has to be inserted in a mediodistal to lateroproximal direction to avoid penetration of the joint. A short screw is used to prevent penetration of the physis. However, the screw is at such a favorable angle, relative to the direction of the tension, that a short screw (22 mm) has adequate holding power. The proximal screw is easily inserted as previously described.

Once the correction is complete and verified radiographically, the implants must be removed through stab incisions over the screw heads, with the horse under short-term anesthesia. The exact location of the screw heads is easily determined radiographically. It is important to be sure that the screwdriver is correctly seated in the hexagonal indentation in the screw head. Otherwise, stripping of the screw head may occur, making removal with a screwdriver difficult or impossible. In that case, a screw removal device (see Fig. 81-13) should be used to remove the screws. The plate or wire is then removed through the proximal stab incision by introducing a curved hemostatic forceps into the hole and walking it off the edge of the hole in the bone, engaging the implant and pulling it through the incision. The stab incisions are closed using 2-0 absorbable suture material in a simple-interrupted pattern.

If implants are inserted in both forelimbs, it is important to remove the implants when each limb is straight. Waiting until both limbs are straight invariably results in overcorrection of one or undercorrection of the other limb. Implant removal can be carried out on an outpatient basis. Antibiotics are not routinely used.

As with growth acceleration, signal molecules from the proliferating and pre-hypertrophic zone in combination with the perichondrium are involved in retardation of the growth plate. It could be shown in rats that compressing the growth plate using surgical staples changed the feedback loop of PTHrP and Ihh, so that the pre-hypertrophic chondrocytes were pushed toward the osteogenic lineage, enhancing osteochondral ossification. After stapling, the Ihh and Ptc molecules were modestly upregulated at 3 days, whereas BMP-2 and BMP-6 were inhibited.

Combination of Growth Acceleration and Retardation

In severe ALD, growth acceleration and growth retardation procedures are combined for a faster and more complete correction. By combining the two techniques, there is a possibility that the deformity can be completely corrected. The advantage of using implants is that they can stay in place as long as they are needed, in contrast to periosteal transection, which has a time-limited effect.

In miniature horses, ALD is frequently diagnosed (Fig. 89-20, A). The presence of complete ulnas and fibulas is the predominant cause of ALD in this species and can be judged as an atavism (see Fig. 89-20, B and C). Early recognition of the problem is important in these animals. Miniature horses have less growth potential than regular horses; therefore, a 5-month-old foal with a moderate ALD will not achieve correction, even if growth acceleration and retardation procedures are combined. It is important to remove a portion of both the ulna and the fibula at the time of periosteal tran-
section. However, the distal epiphyses of the complete fibula and the tibia are not united, and the continuous movement at their junction may result in abnormal development of the lateral trochlear ridge of the talus and associated osteoarthritis (see Fig. 89-20). This problem is not as severe in the carpal region because of the architecture of the distal radius. In selected cases, transfixation of the distal fibular styloid process to the distal tibial epiphysis or metaphysis, or both, is needed to stop movement at the level of the joint. To insert the screws through the distal fibular metaphysis into the tibia, position screw technique (not lag technique) (see Chapter 81) should be applied to prevent alteration of the articular geometry.

Corrective Osteotomy/Osteotomy

Two types of ostectomy have been described in the literature: the closing wedge and the step. Closing wedge ostectomies (Fig. 89-21, A) have been used for correction of diaphyseal and metaphyseal/epiphyseal ALD in foals with closed growth plates. However, the step ostectomy carried out in the sagittal plane and the step osteotomy carried out in the frontal plane are presently the preferred techniques and are discussed here.

The skin incision is carried out over the lateral digital extensor tendon from the top of the MCIII/MTIII to the distal physis. At that point, the incision is continued medially (in a varus deformity) or laterally (in a valgus deformity) toward the MCP joint. The lateral digital extensor tendon together with the periosteum is split longitudinally. Subperiosteal dissection is carried out to gain access to the dorsal aspect of MCIII/MTIII. At the level of the proposed Z-shaped osteotomy, the periosteum is elevated circumferentially around the bone.

The step ostectomy in the sagittal plane removes a vertical wedge from the center of the bone (see Fig. 89-21, B).

The pivot point, which was previously established on radiographs (Fig. 89-22, A) by drawing the longitudinal bisecting lines through MCIII/MTIII and the phalanges, respectively, is identified relative to proper landmarks, and a 3.2-mm hole is drilled across the bone. A second hole is drilled parallel to the first one, approximately 4 cm further proximally. The oscillating saw is used to cut between the two drill holes across the bone. The previously prepared and sterilized aluminum template with the appropriate angle of the wedge to be removed is laid with one limb parallel to the saw cut and compared with the bisecting lines on the radiograph. A second saw cut is then made along the second
limb of the template and parallel to the first one in the sagittal plane. The Z-shaped osteotomy is completed with the proximal cut through the thinner portion of MCIII/MTIII (lateral in a varus deformity) and the distal cut across the opposite side of the bone in a horizontal plane, parallel to the physis. The wedge is removed, and the two bone fragments are rotated into alignment. Final adjustments are made to ensure complete correction of the deformity and bone-on-bone contact at the palmar/plantar aspect of the bone. If an additional rotational deformity is present, it can be corrected at that point by removing an additional bone wedge from the palmar or dorsal aspect of the bone (see Fig. 89-21, C). Cortex screws are applied in lag fashion across the vertical section of the cut to reunite the two fragments of the bone. A bone plate is subsequently applied medially (in a varus deformity) or laterally (in a valgus deformity) to the bone and, along the vertical cut, the screws are inserted in lag fashion (see Fig. 89-22, B and C). The gap at the distal aspect of the osteotomy may be filled with some bone from the removed wedge as a cortical bone graft. The first row of sutures is placed into the split lateral digital extensor tendon using 2-0 absorbable suture material in a simple-continuous pattern. The subcutaneous tissues are closed, followed by intradermal closure of the skin, as previously described. In selected cases, skin sutures are applied.

Postoperatively, the limb is bandaged and supported by a splint or a cast for a few weeks. A cast would be applied in an adult horse, an excitable horse, or a foal whose step osteotomy was carried out near the physis, allowing only a limited number of screws in the distal fragment.

The holes drilled at the proximal and distal ends of the vertical saw cut reduce the concentration of stress at these locations and prevent postoperative fracture development.
The step osteotomy in the frontal plane is carried out similarly (see Fig. 89-21, D). Again, a Z-shaped osteotomy is performed across the bone, but this time the vertical cut is placed in the frontal plane. In this type of osteotomy, no bone wedge is actually removed. Once the Z-shaped osteotomy is completed, the two fragments are rotated in alignment. At that point, lag screws are inserted and a plate is applied to the bone’s dorsal surface. Performing the saw cuts is somewhat more difficult with this technique; nevertheless, careful handling of the periosteum ensures no inadvertent damage to other structures.

Step osteotomies are most frequently carried out in MCIII and MTIII. However, in selected cases, they can be performed in the proximal phalanx or the radius. The major advantages of a step osteotomy over a closing wedge osteotomy are maintenance of the bone length and the ability to create a lag effect across the vertical aspect of the saw cut and achieve good interfragmentary compression.\(^4^6\) This cannot be accomplished in a closing wedge osteotomy. Also, the easy correction of rotational deformities is an advantage.

Step osteotomies are gaining in popularity, and a good prognosis can be given in many cases. The use of 5.5-mm bone screws is encouraged for these procedures.\(^4^5\)

**Prognosis**

Several studies have reported the response to both nonsurgical and surgical treatment of foals with angular limb deformities. One study reported that in 81.5% of foals treated with hemi-circumferential periosteal transection and elevation (HCPTE) to correct angular deformities, total limb straightening was achieved and 60% of foals went on to be used at their intended performance level.\(^3^5,3^6\) In a study that reported the results of transphyseal bridging, 80% of foals with carpal deformities and 27.3% of foals with metacarpophalangeal deformities went on to a form of athletic use.\(^3^8\) The poor results obtained in the foals treated for metacarpophalangeal or metatarsophalangeal deformities were attributed to the fact that several of these foals were operated on near or after the end of the rapid growth phase of the distal third metacarpal or metatarsal growth plate. Racing performance after HCPTE in Thoroughbreds has been reported; treated foals had fewer starts at 2 years of age and lower start percentile ranks.\(^3^2\) However, it is difficult to rely heavily on these comparison numbers, because many foals that have undergone surgery for ALDs are not declared as such in yearling sales. A study reporting the results of treatment in foals with tarsal valgus demonstrated that only 52.4% met the expectations of their intended use, and these authors concluded that foals with tarsal valgus have a poorer prognosis for future athletic use than do foals with carpal deformities.\(^3^0\) Another study showed that foals with incomplete ossification of the tarsal bones and greater than 30% collapse of the third and central tarsal bones had a poorer outcome than did similar foals with less than 30% collapse,\(^3^4\) thereby stressing the importance of early recognition and treatment.

Conflicting results regarding the significance of the location of the pivot point and the presence of radiographic abnormalities in cases of carpal deformities have been published. According to one study, the more radiographic
abnormalities that are seen distal to the distal radial physis and the more distal the location of the pivotal point is, the poorer is the prognosis. In another study, no such correlation could be made. Also, it has been demonstrated that surgical manipulation of distal radial physis growth can cause changes in the angles in all of the carpals. Thus surgical manipulation of physseal growth may be successful in correcting ALDs originating distal to the growth plate (e.g., epiphyseal deformities).

The complex problem of flexural limb deformities appears often in the equine veterinary literature, and its treatment was documented as early as the 5th century AD in the *Mulomedicina* by Vegetius. A flexural deformity represents a deviation of a limb in the sagittal plane and is expressed either as a persistent hyperflexion or hyperextension of a joint region. Persistent hyperflexion has been termed *contracted tendons*, even though in most cases the tendon units are not actually contracted, they are just functionally too short relative to the associated osseous structures. By convention, the type of deformity is named according to the joint involved and not the tendon and is classified as a contractural deformity. Although hyperextension deformities are not part of the flexural deformity complex per se according to the definition for flexural deformities, these problems also are included and discussed in this chapter.

Flexural deformities are encountered in the distal interphalangeal joint, the metacarpophalangeal or metatarso-phalangeal joint, the carpus, and, rarely, the tarsal region. Most often an animal suffers from one type of deformity only, but several areas can be affected in severe congenital contractural deformities. The forelimbs are more commonly affected, and the problem can be encountered in more than one limb at the same time. Flexural deformities present at birth are referred to as *congenital deformities*. Acquired flexural deformities develop during the remainder of the animal’s life.

**PATHOGENESIS**

**Congenital Deformities**

Factors responsible for the development of congenital contractural deformities are shown in Figure 90-1. Some causes mentioned are speculative and lack scientific evidence of their existence. Work is needed to understand the intricate details that lead to the development of such deformities.

Intrauterine malpositioning is a commonly mentioned cause of the problem. This could actually be the case in an abnormally large foal relative to the size of the mare, where intrauterine crowding leads to development of the problem. This, however, is the exception to the rule. More likely, congenital flexural deformities are multifactorial in their origin and hence are difficult to explain.

Diseases acquired by the mare during pregnancy can lead to the development of flexural deformities in the foal. A multitude of agents and causes have been associated with the problem, including ingestion of locoweed and hybrid Sudan grass during pregnancy, a dominant gene mutation in a sire, equine goiter, an influenza outbreak, neuromuscular disorders, and defects in cross-linking of elastin and collagen caused by lathyrism. The evidence in these cases may be only circumstantial, underscoring the need for further investigations into the development of congenital deformities.

An early report stated that 20% of 608 fetuses and newborn foals submitted for necropsy suffered from miscellaneous limb contractures, which underscores the trend noted by clinicians that the incidence of flexural limb deformities is increasing.

**Acquired Deformities**

There are several pathways for the development of acquired deformities (see Fig. 90-1). It has been suggested that acquired contractual deformities are part of the developmental orthopedic disease (DOD) complex, which also includes angular limb deformities, osteochondrosis, physisitis, and cervical vertebral malarticulations or malformations.

It has been postulated that in rapidly growing foals, the longitudinal growth of the bone is greater than the potential of the tendon unit to elongate passively at a corresponding rate. Most acquired contractural deformities are encountered between 4 weeks and 4 months of age and again at the yearling age, an observation that supports the theory. Rapid bone growth occurring between 4 weeks and 4 months can induce a contractural deformity in the distal interphalangeal joint. Passive elongation of the tendon might be limited because of the relatively unyielding accessory ligament of the deep digital flexor tendon, which originates at the proximal and palmar aspects of the third metacarpal bone (MCIII) and joins the tendon in the midmetacarpal region. Passive elongation proximal to that region, therefore, has little influence on prevention of the problem. Because of the functional shortening of the deep digital flexor tendon unit, excessive tension is exerted on the distal phalanx, which results in palmar rotation of the entire foot and the development of the typical club-footed stance.

The rate of bone growth is determined by genetics and nutrition. Foals can be overfed either by heavily lactating mares or by excessive supplementation with concentrates. An abrupt change from inadequate—both in quality and quantity—nutrition to abundant nutrition also can induce the problem in yearlings.

At 3 months of age, growth at the distal MCIII has ceased but continues to occur at the distal radius. The accessory ligament of the superficial digital flexor tendon originates just proximal to the distal radial growth plate from the caudal aspect of that bone. Rapid growth of the radius around 1 year of age can result in a functional shortening of the superficial flexor tendon unit and development of a contractural metacarpophalangeal deformity. This theory was validated experimentally when foals previously kept on a poor ration were fed free-choice high-quality feed at the yearling age and subsequently developed flexural deformity. However, the development of the problem might be more related to nutritional imbalances than excessive high-energy intake.

Kidd and Barr have theorized that longitudinal bone growth is insufficient at any age to create a relative shortening of the flexor tendons. They postulated that rapid
growth increased tension within the flexor tendons and that this could induce pain, ultimately leading to the development of contractual deformities. Contractural deformities often have an acute onset of 24 to 48 hours, which also supports this theory. Whereas muscle contractions can develop in such a short period, bone lengthening would take longer.

A study of skeletally normal foals revealed that most of the cells in the deep digital flexor tendon and its accessory ligament are myofibroblasts. These cells have contractile ability and therefore might play a role in the development of contractural deformities. This leads to pain as the primary inciting factor associated with acquired contractural deformities. Any painful condition could be responsible for the flexion withdrawal reflex and the resultant muscle contraction, leading to an altered stance. Osteochondrosis, arthrosis, infectious joint disease, acute severe trauma to osseous and soft-tissue structures, bruised feet as a result of prolonged exercise on hard ground, and hoof problems are just a few conditions associated with a non-weight-bearing lameness or continuous overload of limbs for prolonged periods. Such painful processes can induce muscle contractions, leading to the development of contractual deformities. Although pain can be the inciting factor in acute-onset contractual deformities, more permanent states of flexion of the musculotendinous unit can occur with contracture of the flexor aspect of the joint capsule and maintain the deformity, underscoring the need for early diagnosis and effective management.

**DIAGNOSIS**

**Congenital Deformities**

A flexural limb deformity, whether a contractual or digital hyperextension deformity, is considered congenital when it is present at birth. The problem is easily recognized in most cases and should be evaluated by a veterinarian at that time.
Digital Hyperextension Deformities

Newborn foals might be presented with a mild degree of digital hyperextension (Fig. 90-2). Such foals might be unable to maintain their toes on the ground: while standing, their metacarpophalangeal or metatarsophalangeal joints are angled more acutely than normal, and the animals are reluctant to ambulate. The problem is caused by flaccidity of the flexor muscles\(^1\) and usually corrects itself within a few weeks because of negative allometric growth of the tendons relative to the bones and increased muscle tone. In severe cases, the foals walk on the palmar or plantar aspect of the phalangeal region, where skin lesions rapidly develop as a result of abnormal loading. These severe hyperextension deformities have to be distinguished from the milder forms\(^2\) and the skin must be protected accordingly.

A radiographic and ultrasonographic evaluation can be helpful in diagnosing the deformity; however, in most cases, no abnormal findings can be detected.

Contractural Deformities

The characteristic stance of foals with contractural deformities makes a diagnosis possible in most instances. The problem may be displayed in various degrees of severity and in several locations. Newborn foals with the deformity located in the distal interphalangeal joint walk on their toes (Fig. 90-3, A). The deformity can also be present in the metacarpophalangeal region. Newborn foals afflicted with this problem are not able to stand on their feet (see Fig. 90-3, B). The carpal region is another location where a deformity may be encountered. Some foals are able to stand but buckle forward in that region; others with severe deformities are not able to stand at all (see Fig. 90-3, C).

The affected area should be palpated and manipulated with the animal in both weight-bearing and non-weight-bearing positions. In most cases the only abnormality noted is the lack of mobility in the affected joint or joint region. An attempt should be made to correct the deformity manually. The resistance toward such an effort is a good indicator of the prognosis and can help in deciding whether to treat a foal. Palpation of the flexor tendons during manipulation is helpful in determining which structures are involved. Both the deep and superficial digital flexor tendons and even the suspensory ligament are often involved.\(^3,4\)

If manual correction is easily obtained, the animal should certainly be treated and has a good prognosis to respond positively to splint or cast management. In foals whose deformities are not manually correctable, the decision to treat depends on the severity of the deformity and prevailing economics. As examples, treatment should be initiated in a foal with a mild contractural deformity of the distal interphalangeal joint that is unresponsive to manual correction, whereas treatment might not be indicated in a foal with a severe deformity in the carpal region\(^3,4\) (see Fig. 90-3, C).

Congenital contractural deformities of the proximal interphalangeal joint are rarely diagnosed and often involve osseous and soft tissue abnormalities.\(^4\) Depending upon the severity of the problem, subluxations and ankyloses of this joint could be diagnosed.

A radiographic evaluation can be helpful in diagnosing congenital contractural deformities to determine whether bony abnormalities are associated (Fig. 90-4).

Ruptured Common Digital Extensor Tendon

This relatively common congenital disorder has some pathognomonic features that simplify the diagnosis.\(^4,5,35\) Afflicted foals display a characteristic swelling in the tendon sheath at the dorsolateral aspect of the carpus (Fig. 90-5). The foal often has a slightly bowlegged and over-in-the-knees stance. This stance is caused by the lack of support at the dorsolateral aspect of the carpus, which is normally conferred by the intact common digital extensor tendon. Therefore, it is not truly a contractural deformity, but it clinically appears as one. The two ends of the partially or completely ruptured tendon can easily be palpated in the tendon sheath. With time, these ends proliferate, making their detection during palpation even easier.

During walking, afflicted animals throw their forelimbs forward, extend them completely, and retract them slightly before contacting the ground. A foal with a ruptured common digital extensor tendon often knuckles at the metacarpophalangeal joint during walking and might buckle in the carpal region while standing. In severe cases the foal may not be able to stand straight without knuckling forward (see Fig. 90-3, B).

Incomplete ossification of the cuboidal carpal and tarsal bones is usually diagnosed concomitantly in foals afflicted with ruptured common digital extensor tendons.

Acquired Deformities

Acquired contractual deformities are seen more often than acquired hyperextension deformities. Continuous overload
of certain limbs can, in selected cases, induce hyperextension deformities. Such problems can also be encountered after ruptures of flexor tendons (see Chapter 86). Flexural deformities develop over time, and careful examination of the animal can allow early diagnosis of the problem, when treatment is less complex.

**Contractural Deformities**

**DISTAL INTERPHALANGEAL JOINT**

Early signs of impending contractural deformity of the distal interphalangeal joint are a steeper dorsal hoof wall angle and a relatively short toe. With time, the typically boxy foot develops, in which the dorsal hoof wall and the heel are practically of the same length. As the heel grows, flexion of the distal interphalangeal joint and hyperextension of the metacarpophalangeal joint increase.

For diagnostic, therapeutic, and prognostic purposes, a classification of deformities has been proposed. A stage I deformity is present when the angle described by the dorsal hoof wall and the sole is less than 90 degrees; in stage II contracture, the dorsal hoof axis passes beyond the vertical. The longer the condition is neglected, the worse the deformity becomes. Permanent changes of the associated soft-tissue structures occur, and the abnormally loaded bones remodel according to Wolff’s law.

**METACARPOPHALANGEAL JOINT**

Acquired contractural deformities of the metacarpophalangeal joint are initially characterized by a straight metacarpophalangeal angle. Palpation of the flexor tendons allows determination of which structure is tightest: the deep flexor tendon unit, the superficial flexor tendon unit, or the suspensory ligament. Application of pressure to the dorsal joint region in a palmar direction tenses the tendons. This diagnostic test is important to help select treatment. Palpation and passive manipulation of the involved region should be carried out with the limb in a non-weight-
bearing position to recognize potential adhesions between the tendinous structures.

Knuckling over in the metacarpophalangeal region is seen in more-severe cases in which treatment has been neglected for a long time. The speed at which such a deformity develops greatly depends on the degree of pain present, the pain threshold of the patient, the growth rate, the amount of exercise allowed, and possibly the foot-trimming techniques employed. It is important to diagnose a contractural deformity as early as possible, and promoting client awareness can be helpful in this regard.

Both front and back limbs can be affected, but acquired metatarsophalangeal joint contractural deformities are much less common than those affecting the metacarpophalangeal joint. Acquired flexural deformities of the metacarpophalangeal joint have also been reported in mature horses secondary to desmitis of the accessory ligament of the deep digital flexor tendon.

PROXIMAL INTERPHALANGEAL JOINT
Acquired contractural deformity of the proximal interphalangeal joint has been primarily diagnosed bilaterally in rapidly growing weanlings. It occurs in foals with straight hindlimb conformation in the same time period as acquired contractural deformities of the metacarpophalangeal joint. The biomechanical basis of the condition has been postulated as shortening of the deep digital flexor musculotendinous unit and a concurrent laxity in the superficial digital flexor tendon, which inserts adjacent to the proximal interphalangeal joint. Usually a dorsal subluxation is diagnosed and is accompanied by an audible click as the foal walks. Radiographs might show osteoarthritis in chronic cases.

Contractural deformities also develop after prolonged periods of not bearing weight, such as that occasioned by radial paralysis or often by conservative fracture treatment (Fig. 90-6). Depending on their management, deformities can become permanent and debilitating despite healing of the original ailment. The joint region involved with the contractural deformity can be fixed by the contracture, without osseous ankylosis present (fibrodesis).
TREATMENT

Congenital Deformities

Digital Hyperextension Deformities

Most foals with mild digital hyperextension do not need treatment other than minimal attention and trimming of the feet.40 The animals should be carefully observed, and if the problem worsens, treatment should be promptly initiated. Moderate exercise is indicated; therefore, access to pasture is allowed. Excessive exercise is contraindicated because fatigue often aggravates the problem.

SWIMMING

Swimming has been advocated as excellent controlled physiotherapy. The animal is supported in a swimming pool or pond by one or two helpers or a rescue net (Fig. 90-7). The paddling action of the foal in the water is carried out against the resistance of the water and without placing weight on the limbs. The resultant increase in muscle tone brings about rapid amelioration of symptoms.

Severe digital hyperextension problems must be treated immediately, because neglect soon leads to necrosis and traumatization of the skin in the palmar or plantar phalangeal region and jeopardizes treatment.

SHOEING

Application of glue-on shoes or similar devices with palmar or plantar extensions helps maintain the hoof sole on the ground (Fig. 90-8). These devices constrict the foot and can cause problems if left in place too long. Application of a splint in combination with extension of the heel can help in treatment. However, care has to be taken not to overprotect the flexor tendons and their associated muscles.

BANDAGING

Light bandaging of the phalangeal region is indicated to minimize skin trauma. Splint bandages and casts incorporating the foot are contraindicated because they totally support the distal limb, leading to a further loss of tone of the already hypotonic flexor tendon units. Additionally, development of pressure sores on the delicate skin is a common untoward sequela.

Application of some padding between the elongated braces attached to the foot and the palmar or plantar aspect of the phalangeal region can supply support and decrease the excessive hyperextension angle. Daily swimming and carefully dosed anti-inflammatory drugs are indicated and should always be part of therapy.

SURGICAL MANAGEMENT

Tenoplasty has been described as a possible surgical management technique for severe digital hyperextension problems in small or miniature foal patients, but it is currently not recommended.42

Contractural Deformities

NONSURGICAL MANAGEMENT

Analgesics

Animals suffering from a contractural deformity, which is a painful condition, benefit from the administration of nonsteroidal anti-inflammatory drugs (NSAIDs). However, these drugs should be given judiciously because of the potentially detrimental side effects, including gastric ulcers and nephrotoxicity. Administration of phenylbutazone at 1.1 mg/kg body weight IV once a day and concurrent treatment with ranitidine (6.6 mg/kg orally three times a day, or 1.5 mg/kg IV three times a day) as a gastric protectant has been proposed.26 Phenylbutazone plus cimetidine is another potentially useful combination of drugs to reduce pain in the treatment period.

Intravenous oxytetracycline

Administration of oxytetracycline has recently become popular as an initial treatment for congenital contractural deformities.43 A single dose of 3 g oxytetracycline in 250 to 500 mL of physiologic saline is administered slowly by the intravenous route. An in vitro study showed that oxytetracycline induced a dose-dependent inhibition of collagen gel contraction by equine myofibroblasts. Oxytetracycline also induced a dose-dependent decrease in matrix metalloproteinase 1 (MMP-1) mRNA expression by equine myofibroblasts. Results of this study indicate that oxytetracycline inhibits tractional structuring of collagen fibrils by equine myofibroblasts through an MMP-1–mediated mechanism.44

In young foals, oxytetracycline administration can make the developing ligaments and tendons more susceptible to elongation during normal weightbearing, resulting in correction of the deformity within 24 to 48 hours. The treatment may be repeated once or twice within the first weeks of life if necessary. No side effects have been mentioned, other than vital staining of the active osteons in the bone.

Mild cases of contractural deformities respond to this treatment with complete correction. In more severe cases or, more likely, those with a different cause, the response is
minimal and care must be taken to ensure that the foals are kept in a well-padded area with soft ground to prevent excessive wearing of hoof horn at the tip of the foot. If that is not possible, protection of the toes may be indicated. Addition of a splint bandage (see later) can support correction.

In a comparative study, a single dose of 44 mg/kg oxytetracycline was administered intravenously to normal newborn foals and newborn foals suffering from flexural deformities. This treatment resulted in a significant decrease of the metacarpophalangeal joint angle in both groups. Within 4 days after the injection the foals regained...
their pretreatment angle. Based on this observation, one report accorded no clinical value to the oxytetracycline treatment of flexural deformities.26

Toe extensions
Application of a dorsal hoof extension using acrylic alone or in combination with a lightweight foot plate protects the toe from excessive wear and increases the tensile forces in the deep digital flexor tendons during ambulation. This probably helps in correcting the problem.

To maintain these devices on the feet, numerous holes of approximately 2 mm in diameter and depth are drilled into the dorsal hoof wall. The hoof acrylic used to achieve the dorsal extension is spread over the dorsal hoof wall and worked into the holes to add stability to the device. The acrylic, interdigitating with the dorsal hoof wall, serves as an anchoring device and prolongs the life of the extensions. Filling in the space between the extension and the dorsal hoof wall decreases the risk of the foal’s stepping on the extensions or stumbling over them.

These devices may be successfully applied in newborn foals with mild contractural deformities of the metacarpophalangeal joints, when the foal cannot bear weight without knuckling over. Extending the dorsal hoof wall adds the necessary elongation to compensate for the lack of extension in the phalangeal region and allows the foal to stand without knuckling. Once the foal is able to ambulate, correction of the deformity is usually achieved within 2 weeks, at which time the extensions typically become detached.

The toes must be protected from excessive wear as foals are allowed free exercise. A special half-round glue-on shoe has been developed for this purpose, with a toe extension built into its design10 (Fig. 90-9).

Splints and casts
Splints and casts are effective for treating contractural deformities. Foals suffering from contractural deformities of the distal interphalangeal joint that are unresponsive to hoof extensions can be treated with half-limb casts, incorporating the feet. This treatment causes relaxation of the muscle–tendon units within a few (10 to 14) days, correcting the problem.3,4,47

Some authors prefer splints applied over casts because they can be worn for several hours followed by a period without splints.26 When the tone has returned into the muscle–tendon units, the animal may exercise, possibly with some concomitant anti-inflammatory drug therapy, and maintain the correction. Casts have to be changed at least every 2 weeks to keep pace with the growth of the foal.

Splints are more difficult to apply in the distal phalangeal region and are not as effective as casts; however, there are fewer complications associated with these devices. Splints are preferably used in contractural deformities of the metacarpophalangeal and carpal region, especially in mild carpal contractural deformities. In these cases care is taken to avoid incorporation of the phalangeal region into the splint.47 Splints have to be well padded and changed every 3 to 5 days. It is important to use new, dry padding at each bandage change to minimize development of pressure sores (Fig. 90-10; see Fig. 90-3, C).

Splints may be used in combination with intravenous oxytetracycline, especially in treatment of severe carpal contractural deformities. These foals are unable to rise and nurse and have to be assisted many times daily.

Stretching of tendons and associated contracted soft-tissue structures (e.g., joint capsules) is painful; therefore, administration of low doses of anti-inflammatory drugs might be necessary. It is advisable to prolong the application intervals to prevent overdosing the patient. The doses should be reduced from the calculated dose per kilogram body weight regimen.

SURGICAL MANAGEMENT
Surgical intervention is seldom necessary with congenital contractural deformities. Surgical transection of the flexor carpi ulnaris and the ulnaris lateralis tendons resulted in the
correction of mild carpal deformities. The surgery is performed under general anesthesia with the foal in lateral recumbency. It is advisable to manipulate the limb immediately prior to surgery, while the foal is under anesthesia, to see if these tendons tighten when forceful carpal extension is applied. The tendons are easily identified and can be transected, if transection is deemed useful, through a small incision between the tendons. Routine aftercare is given to these patients.

Some success has been reported with surgical transection of the palmar ligament and capsule of the middle carpal and antebrachiocarpal joint (see Fig. 90-3, C). The carpal canal is opened through a medial approach; the joints are identified and subsequently opened through a horizontal incision. This author has had little success with this technique on two foals with severe carpal contractural deformity. Release following transection was not adequate.

Ruptured Common Digital Extensor Tendon

NONSURGICAL MANAGEMENT

Foals with ruptured common digital extensor tendons are best confined to a box stall, because they tend to stumble frequently. Within a few weeks, locomotion normalizes and more exercise can be allowed.

Application of a well-padded splint bandage is the treatment of choice (see Figs. 90-3, B, and 90-10). The use of a thermoplastic splinting material (Plastazote, Smith & Nephew, Hull, England) in combination with a polyvinyl-chloride pipe splint has had excellent results. These devices maintain a normal limb axis, which allows ossification of the often dysmature carpal bones to proceed under...
orthogonal loading conditions (see Chapter 89). Additionally, pressure exerted over the distended tendon sheath of the common digital extensor tendon in the carpal region decreases swelling.

The splint bandage is changed every 3 to 5 days over a period of 2 to 4 weeks. During this time, stall rest is indicated. Once the splint is removed, the bandage is maintained for an additional 3 to 4 weeks. Subsequently, the bandage is removed for a day. Should the swelling return, the bandage is reapplied immediately. Should the swelling not return, the bandage is left off another day, and so on, until the limb can be left unbanded. Treatment is adapted to the response of the patient. In some cases, shorter intervals are successful.

In selected cases, full limb or tube casts are applied; however, the advantages of the polyvinylchloride splints are such that cast application for this purpose has decreased in popularity.

Aspiration of the synovial fluid from the tendon sheath is discouraged because of the risk of infection. Continuous external pressure quickly induces absorption of the excess fluid.

**SURGICAL MANAGEMENT**

It is generally accepted that ruptured common digital extensor tendons should not be treated surgically because of the good prognosis and success of splint application. The risk of complications secondary to surgery outweighs any improvement of the prognosis. However, thorough removal of all fibrin clots from the tendon sheath through a surgical incision, followed by installation of a suction drain and cast immobilization, has resulted in excellent cosmetic appearance of the limbs.

**Acquired Contractural Deformities**

**Distal Interphalangeal (Coronopedal) Joint**

**NONSURGICAL MANAGEMENT**

Nonsurgical management includes proper nutrition, physiotherapy, analgesics, application of a toe extension, and application of a cast.

**Nutrition**

Determination of the nutritional intake, especially the calcium-to-phosphorus ratio, is important because an aberrant ratio has been incriminated in the development of contractural deformities. Balanced nutrition is important for normal development of the skeleton and enchondral ossification. Additionally, it is advisable to evaluate soil and drinking water samples for their mineral and trace mineral composition; adjustments should be implemented immediately after identifying inadequate levels. Foals still suckling should be weaned early, especially if they develop an angular limb deformity.

**Physiotherapy**

It is important that afflicted foals exercise frequently. Extensive exercise can stretch the tendons and correct the problem; however, it is important that the toe region is protected to prevent excessive wear and possible development of a septic process.

Analgesics

Passive stretching of shortened or relatively shortened tendons is a painful process. To aid the foil in standing and moving around, nonsteroidal anti-inflammatory drugs are given at low doses. Foals with painful limbs tend to lie down a lot, which can aggravate the contractual problem.

**Toe extensions**

Application of a toe extension or a glue-on rubber shoe is effective for flexural deformities of the distal interphalangeal joint. The purpose of this treatment is protection of the toe and prevention of excessive wear in that region. Additionally, the toe extension moves the weight-bearing surface of the foot farther forward, allowing a later breakover and greater tensile stress on the palmar soft-tissue structures of the phalangeal region.

Simple application of a shoe with a toe extension, without filling or bracing the extension against the dorsal hoof wall with hoof acrylic, can cause frequent stumbling and abnormal flaring of the dorsal hoof wall. Simple trimming of the excess heel of a club-footed foal is contraindicated as the only treatment, because it reduces the weight-bearing surface area and causes more rapid wearing of the tip of the toe. In most cases, a club foot develops initially because of the greater wear at the toe and lack of wear at the heel, not more rapid growth of the heel. Trimming of the heel combined with application of a toe extension and protection, however, can be an effective treatment (see Fig. 90-9).

**Cast application**

Cast application in foals causes temporary weakening of the tendons. The distal limbs of afflicted foals may be covered with a fiberglass cast that incorporates the feet for 10 days to a maximum of 14 days. After cast removal, the weakened tendons allow correction of the problem. Despite the fact that the weakening persists for only a few days, the author has achieved permanent correction of the problem with this technique. However, because of the potential complications associated with this type of treatment, cast application is rarely used.

**SURGICAL MANAGEMENT**

Surgical intervention is indicated in foals unresponsive to conservative treatment and in severely affected foals.

**Desmotomy of the accessory (check) ligament of the deep digital flexor tendon**

The treatment of choice for stage I contractural deformities is desmotomy of the accessory ligament of the deep digital flexor tendon (inferior or subcapsular check ligament) (Fig. 90-11). The ligament may be approached from the lateral or medial aspect of the limb; with bilateral contractural deformity, this allows both surgical procedures to be performed without turning the foil on the table. However, because soft tissue proliferation is often encountered postoperatively, it is generally preferred to perform the procedure from the lateral side. A medial soft-tissue proliferation can be mistaken for a proliferation of the medial vestigial metacarpal bone and considered a blemish. Additionally, the check ligament is more easily identified from the lateral approach.
A 5-cm skin incision, centered at the junction between the proximal and middle third of the MCIII, is made over the deep digital flexor tendon. The subcutaneous tissues are bluntly separated and the tendinous structures identified. With the medial approach, the neurovascular bundle overlying the deep digital flexor tendon and its accessory ligament are identified and reflected away from deeper structures. Palpation of the paratenon surrounding the deep digital flexor tendon allows separation between the two structures.

A curved hemostatic forceps is introduced and advanced following the slightly curved surface of the tendon to the opposite side, where the forceps is spread and turned. The accessory ligament of the deep digital flexor tendon lying palmar to the tendon is elevated to the level of the skin incision. Manipulation of the foot in a dorsal direction tightens the ligament and ensures the isolation of the correct structure. Once the ligament is positively identified, it is sharply transected with a scalpel blade. Dorsal rotation of the distal interphalangeal joint produces a 1-cm gap between the transected ends of the ligament. The gap is inspected and palpated, and any remaining fiber strands of the accessory ligament are transected.

The paratenon, subcutaneous tissues, and skin are closed using 2-0 or 3-0 absorbable suture materials in a continuous pattern. Intradermal placement of the skin suture is advised for a better cosmetic result. Postoperatively, a pressure bandage is applied and maintained for 2 to 3 weeks and changed at 3- to 4-day intervals.

Correction of the deformity is usually observed immediately. In some cases, however, it takes a few days until correction is complete. Occasionally, application of a toe protection or extension is needed. Young foals and those without long-standing contracture are allowed controlled exercise within 3 to 6 days after the surgery. Free pasture exercise is encouraged after 2 weeks. In older foals and those with chronic or severe contracture, limiting exercise for a period of months might prevent excessive fibroplasia at the surgery site. To relieve potential pain, nonsteroidal anti-inflammatory agents may be administered at low dose.

A minimally invasive ultrasonographically guided technique was developed some time ago. This technique can be performed in standing horses. Postoperative fibroplasia occurring at the surgery site reunites the transected ends of the ligament with time. In selected cases, fibroplasia in that region is excessive and results in a cosmetically undesirable appearance. Cosmetically unacceptable results can occur from tendinitis that can be induced from exercise when the tendon has been protected by the contracted accessory ligament for a long time. Tendinitis can be avoided with longer periods of controlled exercise. Daily massage of the swelling can reduce the size.

Long-term follow-up of Standardbred foals treated with a desmotomy of the accessory ligament of the deep digital flexor tendon revealed that young foals (younger than 8 months at the time of surgery) could reach their athletic potential. No foals treated after 8 months of age had a favorable outcome.

**Tenotomy of the deep digital flexor tendon**

Stage II contractural deformities might not correct after desmotomy of the accessory ligament of the deep digital flexor tendon. Tenotomy of the deep digital flexor tendon can be used successfully for correction. Initially, such a tenotomy had been looked at as a salvage procedure; however, several animals have developed into sound riding horses.

Two main sites for the surgical procedure have been proposed. The distal approach centers at the palmar and median aspect of the pastern joint region and enters through the tendon sheath just distal to the bifurcation of the superficial digital flexor tendon. The deep digital flexor tendon is identified, exteriorized, and transected with a scalpel blade. Immediate retraction of the proximal stump into the tendon sheath is noted. The tendon sheath may or may not be sutured using routine technique in addition to the subcutaneous tissue and the skin.

While the animal is under anesthesia, the feet are trimmed to a shape as normal as possible. Postoperative correction is often immediate and can be associated with substantial pain. Administration of nonsteroidal anti-inflammatory agents is therefore routine.
Because of the long time it takes for a stage II contractural deformity to develop, the soft-tissue structures, such as joint capsule, ligaments, and periarticular tissues at the palmar aspect of the phalanges, are significantly contracted. Transection of the deep digital flexor tendon at the level of the proximal interphalangeal joint does not result in a marked elevation of the toe during weightbearing, as it does after rupture of this tendon in the region of the navicular bone. Nevertheless, in selected cases, application of a shoe with a heel extension is necessary.

Transection of the deep digital flexor tendon at the midmetacarpal level is advocated. The procedure is carried out through a medial or lateral approach. The advantage of this approach is the greater distance from the feet and the fact that a tendon sheath is not invaded. Additionally, the procedure is easier to perform at the midmetacarpal level. However, scarring associated with marked disfigurement of the tenotomy site can be an undesirable sequela.

Postoperative management is identical to that used with the other technique.

Metacarpophalangeal Joint
NONSURGICAL MANAGEMENT
Nonsurgical management includes proper nutrition, physiotherapy, analgesics, corrective shoeing, application of a vertical bar shoe, and application of splints.

Nutrition
The nutrition intake of the patient should be corrected first (see earlier discussion). Foals being conditioned for yearling sales should be checked carefully for early signs of contractural deformities of the metacarpophalangeal joint.

Physiotherapy
Hopping an animal is a further attempt to bring about correction of the deformity without surgery. One limb of a foal is elevated and held in that position while a helper leads the animal at a walk. During the support phase of the elevated limb, most of the weight is transmitted to the person holding the limb. The opposite limb is quickly advanced and all the weight brought to bear on it. By repeating this type of physiotherapy several times daily, a potential stretching of the tendons can be achieved. Exercise is an important type of therapy, but it should be carried out in a controlled manner. Excessive exercise leads to fatigue, which should be avoided.

Analgesics
Passive stretching of shortened or relatively shortened tendons as well as the physiotherapy manipulations are painful processes. Nonsteroidal anti-inflammatory agents are applied frequently to manage the pain involved in trying to stretch the tendons and their associated accessory ligaments. As mentioned earlier, foals with painful limbs tend to lie down a lot, which can aggravate the contractural problem.

Corrective shoeing
Corrective shoeing can eliminate contractural deformities of the metacarpophalangeal joint. Raising the heel with wedge pads results in a more acute angle of the
metacarpophalangeal joint as a result of partial relaxation of the deep digital flexor tendon. Some authors have questioned the effectiveness of such treatment, but clinically, an improvement is possible. Toe extensions have been advocated and have proved very effective, especially when the problem was diagnosed early. As the animal walks, breakover occurs later, and through this, greater tensile stress is exerted on the flexor tendons.

**Vertical bar shoe**
Application of a vertical bar shoe in conjunction with the use of a piece of auto tire inner tube just proximal to the metacarpophalangeal joint can be an effective treatment (Fig. 90-13). The soft, stretchable inner tube prevents development of skin sores. Care must be taken to prevent the animal from interfering with the inner bars while moving about if the devices were applied to both forefeet.

**Splints**
Splint application can bring about some correction, especially in early-recognized cases. Care must be taken to prevent development of pressure sores.

**SURGICAL MANAGEMENT**
Horses that are unresponsive to conservative management are candidates for surgical correction. Depending on the result of palpation of the flexor tendons during the diagnostic work-up, the accessory ligament of either the deep or the superficial flexor tendon is transected.

**Desmotomy of the accessory (check) ligament of the deep digital flexor tendon**
If the deep digital flexor tendon was tighter during palpation and manipulation, its accessory ligament should be transected using the technique described earlier (see Fig. 90-11). Application of a preshaped polyvinylchloride half-pipe splint is necessary for 2 to 3 weeks to maintain the metacarpophalangeal angle in the normal range.

**Desmotomy of the accessory (check) ligament of the superficial digital flexor tendon**
Transection of the accessory ligament of the superficial digital flexor tendon should be performed when this tendon was tighter during manipulation. Two surgical approaches have been developed. The surgical landmarks for both approaches are the same and consist of the medial distal physis of the radius, the chestnut, and the cephalic vein. An approximately 10-cm skin incision is centered along the chestnut and made cranial to the cephalic vein. The subcutaneous tissue is bluntly separated, and communicating branches to the cephalic vein are isolated, double ligated, and transected between ligatures.

One surgical technique approaches the accessory ligament cranial to the flexor carpi radialis muscle. The oval foramen in the carpal fascia can serve as the distal border of the desmotomy incision. The carpal fascia is transected carefully, and the ensheathed flexor carpi radialis muscle is identified. Both the cephalic vein and the flexor carpi radialis muscle are displaced using a self-retaining

---

*Figure 90-13. A, A yearling filly with a contractural deformity of the metacarpophalangeal joint. B, This animal was treated with a vertical bar shoe with a toe extension. A piece of tube from a radial auto tire was placed over the two bars to maintain the metacarpophalangeal region in a normal position.*
surgical technique of accessory ligament desmotomy of the flexor carpi radialis tendon. After reflecting subcutaneous tissues, and skin is carried out. Is established, and routine closure of the carpal fascia, appears and the carpal sheath becomes visible. Hemostasis is performed, and care is taken to avoid inadvertent injury to the palmar carpal rete. After transection of the ligament, the radial head of the deep digital flexor muscle is identified. A curved Kelly forceps is placed under the distal border and spread. Transection of the ligament is then performed in a proximal direction. Care is taken to avoid injury to the nutrient artery of the superficial flexor tendon, which enters along the proximal border of the accessory ligament. After transection, the same anatomic structures are visible as mentioned with the first technique. Inadvertent incision of the carpal sheath is of no consequence. Closure of the tendon sheath is carried out using a continuous suture pattern with 2-0 or 3-0 synthetic absorbable material. The rest of the closure is routine.

In severe cases, the accessory ligaments of both the deep and superficial digital flexor tendons are transected. As an additional alternative procedure, desmotomy of the accessory ligament desmotomy of the superficial digital flexor tendon was associated with significantly increased strains on the superficial digital flexor tendon and the suspensory ligament and significant alterations in the angles of the metacarpophalangeal and carpal joints.65 Lengthening of the superficial digital flexor musculotendinous unit after desmotomy of the accessory ligament of the superficial digital flexor tendon can be associated with increased strain on the suspensory ligament.65

Postoperatively, a sterile pressure bandage is applied and maintained for 2 to 3 weeks. The bandage is changed at 3- to 4-day intervals.

In severe cases, the accessory ligaments of both the deep and superficial digital flexor tendons are transected.6 As an additional alternative procedure, desmotomy of the accessory ligament of the superficial digital flexor tendon may be performed for salvage purposes in persistent cases.73 However, subluxation of the proximal interphalangeal joint is to be expected. A stab incision is performed directly over the suspensory branch, the subcutaneous tissues are separated with a Kelly forceps, and a curved tenotome is introduced. By applying pressure with a sawing motion, the previously undermined suspensory branch is transected. Care should be taken to avoid inadvertent injury to the palmar artery and vein and the metacarpophalangeal joint capsule. The skin is closed using a few simple interrupted sutures. The same procedure is performed on the other side of the limb.

Severe contractural deformities following prolonged non–weight-bearing lameness do not respond to desmotomy of either of the two accessory ligaments. Such cases should be treated either with a tenoplasty as the lengthening procedure in both flexor tendons, followed by long-term cast application, or with an osteotomy in conjunction with a fetlock arthrodesis (see Chapter 85).

Carpal Region

NONSURGICAL MANAGEMENT

Foals with long-term debilitating injuries that prevent weightbearing on the limb should be treated with splints early in the convalescent period to prevent development of a contractural deformity. Passive stretching exercises are indicated. These two therapies are combined with controlled exercise if the original injury allows it. A contracture typically occurs suddenly over a few days, after several weeks of not weightbearing on the limb. Therefore, physiotherapy should not be delayed. Care should be taken to prevent development of pressure sores under the splint.

SURGICAL MANAGEMENT

In cases resistant to conservative treatment, tenotomy of the ulnaris lateralis and flexor carpi ulnaris tendons can be performed with good results. The same surgical procedure is performed as described earlier. Passive manipulation of the carpal region at that time demonstrates the greater mobility gained through this procedure.

Postoperatively, a well-padded pressure bandage is applied and a splint centered over the carpal region is
incorporated. While the horse is under anesthesia, the limb is forced into a straight position. The splint bandage is changed at 4-day intervals and maintained for about 2 weeks. Hand-walking exercises are important for the first 3 to 4 weeks. As soon as the animal places good weight on the limb, the splint is removed.

**Proximal Interphalangeal Joint**

**NONSURGICAL MANAGEMENT**

Rest is not an effective management tool in these cases. The periarticular tissues may fibrose in, and eventually the clicking noise is not heard anymore. However, a marked bend at the joint level will be visible. Osteoarthritides could develop, necessitating a pastern arthrodesis to render the animal pain free again.

The clicking sound associated with dorsal snapping of the proximal interphalangeal and metacarpophalangeal area could also be observed in foals with persistent foal hoof at the tip of the hooves, resulting in an elongated hoof configuration. Trimming of the hoof was successful in eliminating the clicking sound and the snapping of the proximal interphalangeal and metacarpophalangeal area. This approach should be tried before a surgical intervention is performed.

**SURGICAL MANAGEMENT**

Surgical transection of the accessory ligament of the deep digital flexor tendon or transection of the tendon of the proximal interphalangeal and metacarpophalangeal area could be observed in foals with persistent foal hoof at the tip of the hooves, resulting in an elongated hoof configuration. Trimming of the hoof was successful in eliminating the clicking sound and the snapping of the proximal interphalangeal and metacarpophalangeal area. This approach should be tried before a surgical intervention is performed.

**COMPLICATIONS**

*Nonsurgical Management*

Splint-associated pressure sores are the most often encountered complication. To avoid such complications, padding is placed around sites of predilection. Once necrosis is present, the local pressure has to be released in that area. Application of a donut-shaped pad around the periphery of the lesion can assist in that effort. Alternate application or temporary removal of the splint may be attempted. Daily topical wound care is necessary, especially in the initial period.

**Surgical Management**

Persistent hematoma formation, especially at the site of transection of the accessory ligament of the superficial flexor tendon, wound dehiscence, and infections are the most common complications encountered after surgical treatment. Whenever fever, leukocytosis, warmth at the surgery site, or increased pain are noted, an evaluation of the incision should be made and the necessary steps taken immediately. For additional information on wound dehiscence, please review Chapter 26.

56. McGeady PA: General discussion following Dr. Cosgrove’s paper, Vet Rec 1955;67:967.
The term osteochondritis dissecans was coined by König in 1887 and used to describe loose or semiloose bodies in joints of young persons that could have three causes: very severe trauma, lesser trauma and necrosis, or minimal trauma inducing an underlying lesion. Although the name and concept have led to substantial confusion from the outset, this categorization is still valid today.

It is the last, and most difficult to understand, of König's categories that is termed osteochondrosis (OC) in the equine veterinary literature. Osteochondrosis represents a disturbance of the process of endochondral ossification without a clearly understood etiology. This disturbance can eventually lead to the formation of semi-loose or even completely loose fragments within a joint.

**THE PROCESS OF ENDOCHONDRAL OSSIFICATION**

In all mammals, the primordial skeleton is laid down first as a cartilaginous structure that, during the entire period of early development of the animal, is coupled in a process of simultaneous growth and transformation into bone. It is important to note that unlike mature articular cartilage, these fetal cartilaginous structures are well vascularized by vessels running through cartilage canals. Ossification of the primary centers of ossification in the diaphyses of the long bones starts early in fetal life, and at the time of birth, all the diaphyses are bony structures. This does not occur in many secondary centers of ossification located in the epiphyses of the long bones and in other sites such as apophyses and cuboidal bones in complex joints, which remain partly cartilaginous at the time of birth.

After birth, longitudinal growth of long bones results from the growth plates or physes where, from a germinal layer of cells (resting cells), chondrocytes proliferate and lay down a scaffold of extracellular matrix. These cells initially hyper trophy and later undergo apoptosis. The scaffold is used for the apposition of primary bone by osteoblasts originating from the metaphysis (Fig. 91-1). This primary spongiosa then undergoes continuous remodeling under the influence of biomechanical loading according to Wolff's law during the entire growth period of the foal. This remodeling con-
OSTEOCHONDROSIS 1167

The growth plate is the interface between cartilage and bone in the long bones of the body. It is characterized by hyaline cartilage, which is responsible for growth and remodeling of the skeleton. The articular side of the epiphysis functions as a type of articular cartilage with the growth plate. Ossification of this cartilage ring takes place first at the border of the physis and at the perimeter of the epiphysis. The thick cartilage mass at the articular side of the epiphysis functions as a type of growth plate where the simultaneous processes of growth, remodeling, and ossification take place that finally result in a considerably thinner layer of articular cartilage in the mature animal. It is at this level that the characteristic lesions of equine osteochondrosis develop.

PATHOPHYSIOLOGY

There is little controversy about the gross pathogenetic mechanism of OC. Disturbances of the process of endochondral ossification result in irregularities in thickness of the epiphyseal cartilage. These create areas of focal weakness, which are exacerbated because the cartilage canals regress with increasing age and have disappeared in the horse by the age of 7 months. This affects the nutrition of the deeper layers of the retained cartilage plugs, which cannot be sufficiently nourished by diffusion from the articular surface and can lead to necrosis. Biomechanical influences, mainly shearing forces, then lead to the formation of fissures and produce cartilage flaps, or detachment of cartilage or fragments of cartilage and subchondral bone. In some locations where biomechanical forces are mainly compressive, infolding of cartilage in these weakened areas can lead to the formation of subchondral bone cysts as another manifestation of OC.

Many caveats concerning this seemingly straightforward mechanism have been made. In an extensive review of pathogenesis and possible etiologic factors of OC, some authors strongly questioned the view that defective ossification lies at the base of all lesions commonly qualified as osteochondrosis in the horse, based on clinical and pathologic observations. One of their major arguments is the observation that after injury, bone and cartilage can manifest only a very limited reparative response. This makes it very difficult, if not impossible, to judge the stage of the process (recently originated or already in some phase of repair) and more so the origin of the lesion (delayed ossification or trauma, for example). Things become even more difficult if one realizes that OC is generally assumed to be a multifactorial disease in which the problem is not to single out a specific causative factor but to determine to what extent, and in which order, a variety of factors play a role. These considerations are discussed in more detail in the section on etiology.

Along similar lines, comparisons between species should be dealt with cautiously. In the late 1970s, in-depth studies on the phenomenon of osteochondrosis in a multitude of species (including horses, poultry, dogs, and cattle, but with the emphasis on swine) concluded that because of the striking similarities in manifestation across the species, including humans, OC should have a common pathogenesis and etiology, the latter being principally growth rate that itself was determined by nutrition and hereditary factors. Ever since, this paradigm of a "seemingly unified hypothesis" has hovered over OC research, and the ease with which conclusions for the horse have been drawn based on research in entirely different species has been remarkable in some instances. It is questionable whether this simple explanation of the pathophysiology of osteochondrosis is justifiable, given many findings from more recent research that are discussed later.

CLINICAL AND RADIOGRAPHIC SIGNS

The typical OC patient is a yearling that is presented with effusion of the tibiotarsal or femoropatellar joint, which has been noted recently by the owner. The horse usually is not lame, and radiographic examination shows a fragment at the cranial end of the distal intermediate ridge of the tibia (Fig. 91-2) or irregularities at the lateral trochlear ridge of the femur (Fig. 91-3). However, as with any typical presentation of a disease, many variations on this theme are possible.
The age at which OC appears varies, although in the great majority of cases OC patients are juvenile animals. In severe cases of OC, which are more common in the stifle than in the hock, signs can be seen in foals as young as 6 months. OC can also manifest itself at the age the animals are put into training and the joints become challenged by athletic activity. The age at which this occurs varies with the branch of equestrian industry. Warmblood horses commonly are presented at about 3 years of age or older, and racing Thoroughbreds and Standardbreds manifest signs much earlier.

Distribution of Lesions

Osteochondrosis is most commonly diagnosed in tarsus, stifle, and metacarpophalangeal joints, but it has been described in almost every diarthrodial joint. In an experimental study, 43 Warmblood foals were used out of pairing OC-positive sires and partially OC-positive mares to produce offspring with a high prevalence of OC. Twenty-four foals were sacrificed at 5 months, all joints were inspected at necropsy, and macroscopic lesions were confirmed by microscopy.9 Lesions were most numerous in the tarsocrural joint (average of two lesions per animal), followed by the femoropatellar and the cervical intervertebral (facet) joints (one lesion per animal), the metatarsophalangeal joint (0.6), the metacarpophalangeal and carpal joints (0.4), humeroradial joint (0.2), and scapulohumeral joint (0.04).10

Although the prevalence of OC in this study was artificially high, the relative distribution is in agreement with clinical experience in the Warmblood. Breed differences occur to a certain extent with regard to lesion distribution and relative clinical importance. Osteochondrosis in the femoropatellar joint is common in the racing Thoroughbred,11 but in Warmbloods and Standardbreds, tarsocrural OC is seen more often.12-16

A hallmark of OC is that lesions almost always occur at certain predilection sites within a joint. In the tarsocrural joint, the most common site is the cranial end of the distal intermediate ridge of the tibia (see Fig. 91-2), followed by the distal end of the lateral trochlea of the talus and the medial malleolus of the tibia.17 In the femoropatellar joint, the most common predilection site is the lateral trochlear ridge of the femur. Less common sites are the medial trochlear ridge of the femur, the trochlear groove, and the distal end of the patella.6 Subchondral cysts that occur in the medial femoral condyle are a manifestation of osteochondrosis as well and are discussed in Chapter 92. The predilection site in the metacarpophalangeal joints is the dorsal end of the sagittal ridge of the metacarpus and metatarsus. Opinions on the nature of the fragments seen at the dorsal margin of the proximal phalanx differ, and the palmar or plantar osteochondral fragments (POFs) that were originally reported as being part of the osteochondrosis complex18 are now considered traumatic in origin.19,20 In the shoulder joint, osteochondrosis is commonly located on the glenoid and the humeral head.21

Lesions are often encountered bilaterally in the tarsocrural and femoropatellar joints and quadrilaterally in the metacarpophalangeal joints.22 Bilateral presence, often with unilateral clinical manifestation only, can occur in the
tarsocrural and femoropatellar joints in more than 50% of clinical cases. Therefore, in horses with unilateral clinical signs, it is advisable to radiograph the contralateral joint. In contrast, concomitant occurrence in other joints or joint pairs is much less common. In a study of 225 horses with tarsocrural OC, lesions were found in other joints in only eight cases. Therefore, joints other than the contralateral one do not need to be radiographed except when clinical signs exist.

Joint effusion is by far the most common clinical sign, but lameness can occur, especially when large radiographic lesions exist. Lameness is seen more in femoropatellar OC than in tarsocrural OC and is most likely when a loose or semiloose fragment is observed radiographically, thus when the osteochondritis dissecans form is present. Other, less-severe radiographic signs include irregularities in the articular contour of the subchondral bone and sometimes only a flattening of this contour.

Minor radiographic aberrations can be reliably classified as OC when judgments are made by an experienced radiologist. In one study, there was a correlation of 0.87 (P < 0.001) between radiographic classification of OC of the distal intermediate ridge of the tibia on a 0 to 4 scale and histology. Nevertheless, the lesion severity as determined radiographically does not always correspond with arthroscopic or necropsy findings. In many cases, cartilage lesions are more severe than radiographic appearance suggests, or cartilaginous lesions are present without changes in the subchondral bone and hence do not show up on radiographs (Figs. 91-4 and 91-5). Severity of lesions can be assessed more accurately with more sophisticated imaging modalities such as magnetic resonance imaging (MRI). However, economic and physical constraints severely limit the wide clinical use of this kind of equipment, especially in the femoropatellar joint.

**Breed Predilection**

Osteochondrosis is common in many breeds of horses. In Swedish Standardbreds, Sandgren and colleagues found an incidence of 10.5% in the hock joints, which was comparable to the 12% found by Schougaard and coworkers but less than the 26% found earlier by Hoppe and Philipsson, also in Standardbreds. Alvarado’s group found an incidence of 35% in the femoropatellar and metacarpophalangeal joints of Standardbreds in a US population. There are fewer studies in Thoroughbreds, but the incidence in that breed is reportedly high as well.

In the Warmblood horse, early Swedish data mentioned an incidence of 15%; more recent figures in the Dutch Warmblood population are higher (25% in the tarsocrural joint and 15% in the femoropatellar joint). In a large study of 1180 horses in France (mainly Selle Français and Anglo-Arabs, a minority of Thoroughbreds), an incidence of 13.3% was reported in the tarsocrural joint. A recent large-scale field study in Germany in several Warmblood breeds yielded figures of 19.5% for the metacarpophalangeal joints, 11.1% for the tarsocrural joint, and 7.2% for the femoropatellar joint.

Overall, it has been estimated that in northwestern Europe alone annually 20,000 to 25,000 foals are born that will develop some degree of OC. Osteochondrotic lesions are only rarely encountered in ponies. Further, in a survey of 80 feral horses, extremely low incidences of 2.5% were found in the tarsocrural joint and 0% in the femoropatellar joint. Because osteochondrosis is a relatively new disease (see next section), these observations strongly implicate breeding policies and possibly management aspects as key factors in this disease.

Osteochondrosis is a debilitating disease only in exceptional cases, where lesions are so extensive that no repair is possible. Nevertheless, the ailment has a strong impact on the economics of the equine industry, and to a certain extent on animal welfare, because tens of thousands of animals are operated upon each year. Apart from the direct economic loss, there is an even larger indirect cost of the disease, because many studbooks will not approve horses with (major or minor, depending on studbook policy) evidence of OC. It has been estimated that the strict breeding policy of the Royal Dutch Warmblood Studbook (KWPN) precludes 30% of all potential male breeding stock from participating in the selection procedures for becoming an approved sire. Apart from direct financial loss for the breeders, this also eliminates a large part of the gene pool. A last, but not insignificant, economic impact of OC is the loss...
in value of animals showing radiographic evidence of OC, regardless of their athletic capacities.

CHANGING CONCEPTS

In 1947 Nilsson, who described fragments in the stifle joints of Ardenner horses, gave the first description of what is retrospectively judged to have been OC.31 Although in the following decades some reports describe intra-articular fragments that might have been osteochondrotic,32 the real history of OC does not start before the publication of Birkeland and Haakenstad’s paper in 1968.33 These authors described a series of seven cases of OC of the distal ridge of the tibia, but they did not use the term osteochondrosis. In the early 1970s gradually more publications appeared,34,35 and in the mid-1970s Olsson and Reiland with other Scandinavian coworkers published their comprehensive study on osteochondrosis in a multitude of species.8,36-39 Osteochondrosis was originally seen as a largely static condition, but this concept gradually changed. Strömberg reported changes in the radiographic appearance of femoropatellar OC after repeated radiographic examinations.40 Dabareiner and colleagues recognized, after sequentially radiographing a number of foals, that osteochondrotic lesions of the distal femur could progress until the age of 9 months.41 In the same year, Carlsten’s group published a study in which they followed a cohort of 77 horses radiographically and found that no major osteochondrotic lesions in the tarsocrural joint were identified after 8 months of age. Interestingly, they noted a regression of a number of minor lesions before the age of 8 months, which had been detected between ages 1 and 3 months.14

Dik and colleagues radiographed the tarsocrural and femoropatellar joints of 43 foals on a monthly basis from the age of 1 month until age 5 months and of 19 of them until age 11 months. The study showed that not only minor lesions but also radiographically visible larger fragments ceased to exist. The ages at which lesions originated and the ages at which they became undetectable varied for each joint. In the tibiotarsal joint, lesions at the distal intermediate ridge of the talus and at the distal aspect of the lateral trochlear ridge of the talus were seen within the first few months of life and became undetectable before the age of 5 months. Thereafter no major changes occurred and existing lesions remained visible. In the femoropatellar joint, lesions originated later and peaked at approximately 6 months before declining in number until about 8 months, after which the lesions remained stable14 (Fig. 91-6).

In a study in another group of Warmblood foals that was followed for 24 months, this general joint-specific pattern was confirmed.35 In that study, very little change in radiographic appearance was noted from 12 to 24 months. Further confirmation of these patterns resulted from two studies. In one study, groups of horses were used to evaluate the relationship between liver copper content and OC,23 and in the other study the influence of nutrition on OC was examined in the French Saddlebred.44 The latter study also featured sequential radiographic examinations.

All these observations have led to the conclusion that OC is by no means a static condition, but in contrast is an extremely dynamic one in which lesions appear and apparently heal during the first months of life.45 The acknowledgment of the dynamic character of OC has led to a profound change in the concept of this disease.

It is well known that the extracellular matrix of the articular cartilage goes through a phase of rapid remodeling in the neonatal animal. It is in this period that the topographic heterogeneity in biochemical composition that is necessary to withstand the locally different biomechanical challenges develops through the process of functional adaptation.46,47 In this process, the collagen network of the articular cartilage is molded under biomechanical influences in a process not unlike that in bone.35 However, whereas bone retains its capacity to remodel throughout the life of
the horse, cartilage metabolism decreases quickly in the early juvenile period, and turnover times are very long in mature horses.\textsuperscript{48,49} The latter fact precludes any substantial remodeling or repair and makes the formation of the collagen network in the early juvenile phase a once-in-a-lifetime process that can have very important consequences for disease prevention in future life.\textsuperscript{50} The sharp drop in collagen metabolism in the early juvenile period determines when the window for repair of lesions closes. Some lesions, either because they originate too late or are too large, do not have enough time for repair. These are the lesions that might eventually become clinically manifest. This means that in OC, a clear distinction should be made between the pathogenesis triggered by a number of etiologic factors on the one hand and the repair process on the other.\textsuperscript{5,52} A flow chart for the putative mechanism of OC based on this concept is given in Figure 91-7.

**ETIOLOGIC FACTORS**

Osteochondrosis is a complex disease and multifactorial in origin. Biomechanical influences, exercise, failure of vascularization, nutrition imbalances, and genetic influences have all been incriminated and are probably interrelated.

**Biomechanical Influences**

Biomechanical loading plays a role in the pathogenesis of osteochondrosis. This assertion is supported by the consistency of predilection sites within specific joints. It is probable that the dramatic changes in biomechanical loading that take place after birth are an important trigger factor for initiating lesions. In a pathologic study of the stifles and hocks of nine fetuses and 10 foals aged 0 to 35 days, Rejnö and Strömberg found an osteochondrotic lesion in only one 3-day-old foal and none in any of the fetuses.\textsuperscript{38} Other attempts to find osteochondrotic lesions in fetuses have failed.\textsuperscript{53,54} Therefore, biomechanical loading most likely plays a role in all proposed mechanisms for OC.

Biomechanical loading can exert an influence late in the process, where it determines the formation and loosening of cartilage flaps after a faulty endochondral ossification, or early where it prematurely disrupts the vascular supply to neonatal cartilage (see next section). Biomechanical influences are strongly correlated with other etiologic factors such as exercise and genetics (through the determination of conformation of the animal). However, apart from direct blunt trauma that will cause an osteochondral fracture, biomechanical forces are considered a necessary additive factor rather than a sole cause of OC.

**Failures of Vascularization**

Wheeler Haines\textsuperscript{55} described the existence of cartilage canals in the epiphyseal cartilage long ago. He stated that “the primary function of cartilage canals is . . . the nutrition of cartilage too large to be supplied by diffusion of nutriments through their substance. . . . Their presence retards rather than hastens the end of ossification.” He also described the process of obliteration of these canals, called *chondrification*, that precedes ossification.

In the pig, extensive studies have been performed on the vascularization of cartilage, the physiologic process of regression of cartilage canals, and disturbances thereof as possible causes for OC. In this species, areas of chondronecrosis related to obliterated cartilage canals can be found, and they are much larger in commercial pig breeds than in miniature pigs from wild hog ancestry.\textsuperscript{56} Artificial devascularization creates islands of cartilage without vascular supply, and these could create OC-like lesions.\textsuperscript{57} These observations led to the hypothesis that premature interruption of the vascular supply of the growth cartilage of the articular–epiphyseal complex would lead to necrotic areas in the cartilage layer. These would later become engulfed in the ossification front and result in the typical irregularities and cartilage islands seen in OC.\textsuperscript{56}

Later in-depth studies in this same area employed a more subtle and natural way of interrupting vascularization, in which only a limited number of cartilage canals was sectioned, which produced OC-like lesions.\textsuperscript{59} No relationship between the overall regression pattern of cartilage canals and OC was shown. This led to the conclusion that OC is not the result of a general failure in endochondral ossification, and hence cannot be caused by a systemic factor such as growth rate, but is incited by local biomechanical factors.\textsuperscript{60} This finding led, together with additional observations, to the hypothesis that OC was caused by local biomechanical damage to cartilage canals, especially to the anastomosing branches that run through the ossification front from the bone marrow.\textsuperscript{52}

In the horse, cartilage canals are present in the juvenile period as well, and it is tempting to extrapolate the pathogenetic mechanism that now seems firmly established in the pig to the horse. However, there are several distinct interspecies differences. Focal islands of chondronecrosis seen in the pig are not frequent findings in the horse and are not a feature of the histologic description of OC, as given by Henson and colleagues.\textsuperscript{62} Although Carlson’s group\textsuperscript{5} showed a few necrotic areas near the ossification front, most of the irregularities and cartilage cores contain viable cartilage, not necrotic cartilage. This was supported by Shingleton and coworkers\textsuperscript{63} in their study on equine cartilage canals, where they found patent canals in retained areas of viable cartilage. This led them to conclude that retention of cartilage canals, rather than disruption of them, might be necessary for the development of OC. Necrosis of cartilage would be the sequela, rather than the initiating factor.
Exercise

Exercise is known to be the steering factor in the process of functional adaptation during which the biochemical composition of the extracellular matrix of articular cartilage takes on a topographically heterogeneous character.\(^{47,48,49}\) This process takes place principally in the first year of life, with emphasis on the first few months. Given the important role of exercise in the juvenile period for cartilage development, it may be hypothesized that this factor would be of importance in the development of osteochondrotic lesions too, because these originate in the same period that articular cartilage composition is molded.

Preliminary research in which controlled exercise was given to foals from 3 to 24 months of age using a high-speed horse walker yielded promising results. Osteochondrosis incidence was 6% in the high-exercise group and 20% in the low-exercise group, but results were flawed because of a concurrently running nutritional study employing different energy levels that were not consistently implemented.\(^{50,51}\) A study focusing on the effect of exercise alone, given from 10 days until 5 months of age, did not yield conclusive results, although there was a tendency toward a decrease in severity of OC lesions in the exercised groups.\(^{52}\)

In a large field study, Wilke found fewer OC lesions on the distal sagittal ridge of the metacarpus and metatarsus in the metacarpophalangeal and metatarsophalangeal joints of foals that got more exercise during the first months of life. There was, however, no effect on the incidence of OC in the tarsocrural joint.\(^{68}\) Exercise might be a factor codetermining the final appearance of osteochondrotic lesions, but does not seem to be of primary pathogenetic importance.

Nutrition, Hormonal Factors, and Growth Rate

From the start of research into equine osteochondrosis, much effort has been dedicated to nutritional factors. The studies can be roughly divided into research on minerals and trace elements, mainly copper and zinc, to a lesser extent calcium and phosphorus, and on dietary energy level. The latter factor is closely related to growth rate, a factor heavily incriminated in OC pathogenesis in a large number of species. However, growth rate is determined not only by energy intake but also by genetic predisposition.

Interest in trace elements was raised by a report on the relationship between low copper levels in serum and ceruloplasmin and OC.\(^{80}\) Studies followed on the effect of deliberately feeding low-copper diets\(^{20}\) and the possible role of zinc in inducing a relative copper deficiency.\(^{1}\) The mechanism was thought to act via the enzyme lysyl oxidase, a copper-dependent enzyme that is essential for the formation of collagen cross-links. Zinc, as well as cadmium, can antagonize copper by displacing it from the sulfhydryl binding sites on metallothionein.\(^{72}\)

The epidemiologic studies on dietary mineral and trace element levels and the occurrence of developmental orthopedic disease in Ohio and Kentucky seemed to give further evidence for a key role of copper.\(^{73}\) The original National Research Council (NRC) recommendation\(^{74}\) of 10 ppm copper in dry matter, which was based on a study with a limited number of horses,\(^{75}\) was challenged, and supplementation studies were started. These yielded positive results to some extent,\(^{76-78}\) but they certainly were not conclusive enough to pinpoint copper deficiency as a sole cause of OC.\(^{79}\) Higher dietary copper levels of 20 to 25ppm\(^{80}\) or 50 ppm\(^{81}\) were recommended, but they were later questioned following studies by Pearce and colleagues, who found that copper levels of 4.3 to 8.6 ppm in pasture were sufficient for a healthy development of bone and cartilage. Supplementation of copper to pregnant mares raised liver copper levels in both mares and foals at 150 days of age, but they did not abolish the occurrence of developmental orthopedic diseases.\(^{82-83}\)

The proposed mechanism via lysyl oxidase was challenged\(^{84}\) as in vitro research yielded additional information on the role of copper that appeared to have a chondroprotective effect through reduction of the activity of the proteinases cathepsin B and cathepsin D.\(^{85}\) Another study showed that there was a relationship between neonatal liver copper concentration and the resolution of lesions, but there was no correlation with the initial occurrence. It was concluded from that study that copper had a positive effect on the repair of osteochondrotic lesions but not on their pathogenesis. This concept could explain many of the somewhat contradictory and inconclusive earlier findings. Copper retains a clinically important role because it is the outcome of both the pathogenetic process and the ensuing repair process that determines the eventual and clinically important lesions.\(^{86}\)

High calcium levels did not influence the incidence of OC in foals, but high levels (four times the NRC recommendation) of phosphorus resulted in significantly more lesions.\(^{86}\) The mechanism was supposed to be the induction of secondary hyperparathyroidism, which would lead to increased osteoporosis and subsequent weakening of the subchondral bone. The study is interesting because foals were studied in the period from 2.5 to 6.5 months of age, which is now known to be a period in which the dynamic process of OC is very active.

Dietary energy levels have been implicated in the pathogenesis of OC for decades.\(^{87}\) This was mostly, but not solely, in relation to a high growth rate. In the early Scandinavian studies, it was stated that OC primarily occurred in large-framed, fast-growing animals, be they broilers, bulls, dogs, swine, or horses.\(^{8,40,41}\) Later, the literature is more ambivalent on the subject of growth rate. Several authors found no relation to growth rate,\(^{2,87,89}\) but others reported a larger prevalence in horses taller at the withers\(^{15}\) or in horses having a higher average daily weight gain.\(^{80}\) Sometimes this was true only for a limited period of development.\(^{88}\)

Although the data about the effect of growth rate is conflicting and the concept of a high growth rate putting pressure on the process of endochondral ossification and thus leading to irregularities might be too simplistic, there is substantial evidence for other mechanisms. Excessive levels of energy, especially when fed in the form of easily digestible carbohydrates,\(^{92,93}\) result in a strong postprandial hyperinsulinemia. Insulin and its derivatives insulin-like growth factor (IGF) I and IGF-II have a direct effect on the process of endochondral ossification, acting as mitogens for chondrocytes and stimulating chondrocyte survival or suppressing apoptosis.\(^{94}\)

Insulin also stimulates a rapid removal from the circulation of the thyroid hormones T\(_4\) and T\(_3\),\(^{95}\) which are involved in the final stages of chondrocyte differentiation.
and in the metaphyseal invasion of growth cartilage by blood vessels.89 In fact, OC-positive foals have a significantly lower IGF-I activity than OC-negative foals.97 In this way, high carbohydrate levels would induce a transient relative hypothyroidism and hence a retardation of the maturation of growth cartilage. Hypothyroidism in horses has been known to produce skeletal lesions, although they are not equivalent to those seen in OC.58

Interestingly, the effect of carbohydrates on thyroid hormone levels can be demonstrated in weanlings, but is not present in yearlings.59 It has been possible to induce cartilaginous lesions by administering diets with high levels of digestible energy.66,100 Further, horses with OC have been shown to have higher postprandial glucose and insulin responses to feeding high-grain ratios than did normal horses.101

Another indication of the importance of carbohydrate levels in the feed comes from a study in Kentucky on the influence of the season on the occurrence of OC. Early foals appeared to have a significantly higher incidence of OC in the tarsocrural joints, but late foals had a higher incidence in the femoropatellar joints. This seemingly contradictory effect of the season could be explained by the different windows of vulnerability of these joints, which appeared to coincide with the spring and autumn peaks in the high-energy value of the grass.27

There is hardly any doubt that the pathogenetic mechanism outlined here plays a certain role in the development of equine osteochondrosis. However, it is unlikely that it is the sole mechanism, because many lesions provoked by the administration of high-carbohydrate diets were similar, but they were not always identical to those seen in clinical OC. Besides, many lesions were seen in the growth plate,86 and in contrast to other species, clinical OC is rarely, if ever, seen in the growth plate in the horse.

**Genetics**

In many species, the incidence of OC varies considerably with breed. In wild boars, the disease seems to be non-existent, whereas it is common in many commercial pig breeds.58 In horses, lesions are rarely found in ponies and have a much lower incidence in feral horses.29,30 This suggests a considerable genetic influence. Further evidence comes from studies showing large differences in incidence of OC between progeny groups of different stallions.13,39,102

There is no doubt that OC is a polygenic trait and that the method of inheritance is complex.103 Some estimates on heritability have been made, but they differed widely. For the tarsocrural joint, heritabilities of 0.24,104 0.26,11 and 0.57105 have been reported. A large progeny study in the Netherlands succeeded in establishing reliable heritabilities for navicular disease and bone spavin, but it did not give unequivocal results with respect to tarsocrural OC, which finally was estimated to be approximately 0.25.106

Heritabilities of 0.25 and higher are high enough to warrant selection programs, which indeed have been implemented by many studbooks. However, progress has been disappointing. The Royal Dutch Warmblood Studbook (KWPN) has rejected any candidate sire with even the slightest radiographic sign of tarsocrural OC since 1984 and any sign of femoropatellar OC since 1992, but no substantial decrease in incidence has been realized thus far. This is in contrast to the conditions of navicular disease and bone spavin, where a similar selection policy has been followed and resulted in a drastic reduction of the incidence of these orthopedic diseases.

There are various explanations for this. Osteochondrosis is classically seen as an all-or-none trait with an underlying continuous scale.103 The genetic background may, however be much more complicated than originally supposed. First, there is mounting evidence that different genes are involved in different joints.89,107 Second, the dynamic nature of OC allows many animals to be radiographically free of lesions at age 3 or 4 years when they enter the stallion selection procedures, yet they will have had evidence of the disease as a foal. Hence, they are genetically predisposed to OC and will pass on this trait.

Recently, studies have been undertaken to identify OC-related genes through modern molecular genetic techniques. These studies are difficult because they try to link the final phenotype, and thus the end product of various processes that most probably have different genetic backgrounds, to certain genes. It is highly unlikely that in the near future OC can be selected against using a simple genetic test that detects one or two culprit genes. Early results confirm the complexity of the disease because various candidate genes have been identified that differed per affected joint.108

**THE MOLECULAR MECHANISM OF OSTEochondrosis**

The need for a more fundamental approach to understanding and preventing osteochondrosis is obvious,109 and in recent years most research on equine OC has focused on the molecular mechanisms involved. Both chondrocyte behavior and composition of the extracellular matrix have been targets of study. Lillich and colleagues found changes in proteoglycan composition of osteochondrotic fragments, but they could not tell whether this was primary or secondary.110 This is a constant problem, because data from clinical cases and fragments collected at surgery are not representative of the initial phase of the disease.7 Studies have focused on normal and abnormal (dyschondroplastic) cartilage, on the expression of various collagen types that are represented in the extracellular cartilage matrix (collagen types II, VI, and X), and on the expression of growth factors (transforming growth factor-β, IGF-I, IGF-II) that are known to play a role in the development and maturation of cartilage.82,84,111

There appeared to be distinct differences in expression patterns between normal and abnormal tissues, with notably high levels of activity around the chondrocyte clusters or chondrones in early cases of OC. This increase in activity is in line with the higher level of chondrocyte metabolism demonstrated by van den Hoogen and colleagues15 and could be the primary cause, but is more likely a secondary event representing an attempt at repair.116 Little work has been done on the subchondral bone underlying the cartilage defects. Van de Lest and coworkers showed changes in bone morphogenic enzymes and in membrane lipid composition of the cellular components of the subchondral bone.117

Levels of matrix metalloproteinases (MMPs) were found to be elevated in copper-deficient horses with clinical OC
lesions, and there is increasing evidence that changes in collagen metabolism play an important role in the molecular mechanism of OC. The Cambridge group performed in-depth studies on the distribution of cathepsins B, D, and L in normal and abnormal cartilage. They found physiologic differences in distribution as well as a strong increase in cathepsin B activity in chondrocyte clonal clusters in OC. Al-Hizab and colleagues showed an increase in activity of gelatinases (MMP-2 and MMP-9) in osteochondrotic cartilage. The increased collagen turnover in osteochondrotic cartilage is reflected by an increase in collagen split products that can be detected in the synovial fluid. Laverty’s group showed an increase in the C-propeptide of collagen type II in synovial fluid from OC horses but a decrease in the epitope 846 of aggrecan, demonstrating different alterations in aggrecan and collagen turnover in OC. This finding was confirmed in a later ex vivo study where no evidence was found for an increase in proteoglycan metabolism, but an increase in the levels of the collagen degradation product hydroxyproline in synovial fluid from horses with OC compared to OC-free animals and by the demonstration of differences in posttranslational modifications of collagen type II in samples from early lesions. Overall, there now seems to be conclusive evidence that changes in collagen metabolism play a crucial role in the molecular mechanism of osteochondrosis. The question of whether this is a secondary or a primary event remains unanswered.

Parathyroid hormone related peptide (PTH-rp) and Indian hedgehog (Ihh) have a role in controlling cartilage remains unanswered. The Cambridge group performed in-depth studies on the distribution of cathepsins B, D, and L in normal and abnormal cartilage. They found physiologic differences in distribution as well as a strong increase in cathepsin B activity in chondrocyte clonal clusters in OC. Al-Hizab and colleagues showed an increase in activity of gelatinases (MMP-2 and MMP-9) in osteochondrotic cartilage. The increased collagen turnover in osteochondrotic cartilage is reflected by an increase in collagen split products that can be detected in the synovial fluid. Laverty’s group showed an increase in the C-propeptide of collagen type II in synovial fluid from OC horses but a decrease in the epitope 846 of aggrecan, demonstrating different alterations in aggrecan and collagen turnover in OC. This finding was confirmed in a later ex vivo study where no evidence was found for an increase in proteoglycan metabolism, but an increase in the levels of the collagen degradation product hydroxyproline in synovial fluid from horses with OC compared to OC-free animals and by the demonstration of differences in posttranslational modifications of collagen type II in samples from early lesions. Overall, there now seems to be conclusive evidence that changes in collagen metabolism play a crucial role in the molecular mechanism of osteochondrosis. The question of whether this is a secondary or a primary event remains unanswered.

Parathyroid hormone related peptide (PTH-rp) and Indian hedgehog (Ihh) have a role in controlling cartilage differentiation and hypertrophy in the growth plate. This influence is mediated by bone morphogenic proteins as signaling peptides. This led to the hypothesis that these molecules would have a similar role in cartilage differentiation in the equine articular–epiphyseal complex and could be implicated in the pathogenesis of OC. There was indeed a significant increase of PTH-rp protein and mRNA expression in chondrocytes from OC-affected cartilage, but not in Ihh. Expression of bone morphogenic peptides 6 and 2 was not changed.

TREATMENT OF OSTEOCHONDROSIS

Nonsurgical Management

Treatment of small osteochondrotic lesions might not always be necessary. Single small, radiographically obvious OC lesions in the tarsocrural joint without effusion did not influence performance in racing Standardbreds, in contrast to joints where there was significant effusion. There was a negative effect on performance, however, if the lesions were more severe. Trotters with OC lesions in the tarsocrural joint had a significantly lower number of starts and somewhat lower earnings compared to controls. Treatment may be either conservative or surgical. Conservative treatment consists principally of rest and controlled exercise. Systemic NSAIDs and intra-articular medication (corticosteroids to enhance resolution of joint effusion and certain disease-modifying osteoarthritic drugs such as hyaluronic acid, chondroitin sulfate, or pentosan sulfate) may or may not be given, but they have not been reported to be of great value in OC. Given the nature of the disease described earlier, conservative management can only be expected to be successful in either very young animals, where there is still good capacity for regeneration, or in very mild cases.

A large study on the natural history of femoropatellar OC in three crops of Thoroughbred foals showed improvement and repair of several lesions, which was compatible with the age of the animals studied. Laws and coworkers described a favorable outcome of conservative treatment of tarsocrural OC in a group of Standardbreds, half of which were treated conservatively and half surgically. The authors mentioned, however, that these results were biased, because the more severe cases tended to be treated surgically.

Peremens and Verschooten concluded that conservative treatment of tarsocrural OC (consisting of simple box rest or a less-intense training program with a low-energy diet) was a good option in Warmbloods (80% success rate), but not in Standardbreds (25%). It should be noted that in Warmblood horses, especially those destined for dressage, resolution of joint effusion is often a therapeutic goal in itself. This aspect was not classified as such in this study.

Surgical Management

Surgical treatment is the treatment of choice in most cases. Clinical experience has taught that arthroscopic surgery presents definite advantages over arthrotomy. Soft-tissue trauma is less, the convalescent period is considerably shorter, and functional and cosmetic recovery are better. An additional advantage is that a more comprehensive examination of the joint is possible. In a direct comparison of arthroscopic treatment and treatment by conventional arthroscopy, Vatistas and colleagues demonstrated that hospitalization time was almost five times shorter after arthroscopy than after arthrotomy. Even more important, horses returned significantly more often to their intended use.

Arthroscopic surgery is widely used at present in the femoropatellar, tarsocrural, and metacarpophalangeal and metatarsophalangeal joints to treat OC. In some other joints where OC is encountered less often but can present a serious clinical problem, such as the scapulohumeral joint, an arthroscopic approach is feasible too, but the technique is considerably more difficult. The surgical techniques applied are discussed in more detail in Chapter 14 and in the relevant chapters discussing the respective joints.

PROGNOSIS

The prognosis after surgical intervention varies between joints and depends on the amount and extent of the lesion. It further depends on the definition of “favorable outcome.” In most racing Thoroughbreds and Standardbreds, a favorable outcome means a sound horse that can compete
at its maximal athletic capacity. In many show horses, the cosmetic appearance is important as well. In general, prognosis for a return to athletic activity is fair to good for the majority of joints involved.

For the femoropatellar joint, Poland’s group reported a 64% success rate, but this figure might be too pessimistic because the study included many horses operated on at a young age before their first performance. Therefore, it included a number of horses that would never have raced despite the OC lesions because attrition rates in Thoroughbred training are high and many young horses will never race. Jockey club records indicate that only about 60% of all Thoroughbreds intended for racing ever reach the starting gate in the United States.

In another study, 19 of 25 arthroscopically treated horses (76%) were able to perform their intended use. Racing performance in Thoroughbreds treated for femoropatellar OC was not different from that in unaffected siblings, but fewer horses raced as 2-year-olds and earnings were less, both at 2 and 3 years of age. Also, 2-year-old Thoroughbreds and Standardbreds that were operated on for OC in the tarsocrural joint were less likely to race, compared to unaffected siblings at 2 years of age, but findings were not different between groups at 3 years of age. The differences might be mainly the result of the delay in training caused by the surgery.

McIlwraith and colleagues reported success rates of 73% and 83% for the tarsocrural joint in racehorses and non-racehorses, respectively. Synovial effusion resolved in 89% and 83% for the tarsocrural joint in racehorses and non-racehorses, respectively. Synovial effusion resolved in 89% and 83% for the tarsocrural joint in racehorses and non-racehorses, respectively.

In the metacarpophalangeal and metatarsophalangeal joints there is some confusion about the extent to which radiographically detectable lesions are part of the OC complex. Fragments of the dorsal aspect of the distal metacarpus and metatarsus are commonly accepted to be osteochondral, and in these, 57% success has been reported after surgery. This figure is negatively biased because 18% of the cases were classified as unsuccessful for other reasons that made the horse unsuitable for use. A more recent source mentions 90% return to athletic activity if the lesion is located in the more proximal part of the sagittal ridge but an unspecified lower rate for lesions in weight-bearing areas. Prognosis for arthroscopic removal of osteochondral fragments of the dorsal articular margin of the proximal phalanx, of which the osteochondrotic nature is still contentious, is given as nearly 100%.

CHAPTER 92

Subchondral Cystic Lesions
Brigitte von Rechenberg  Jörg A. Auer

DEFINITION
Subchondral cystic lesions (SCLs) are commonly referred to as subchondral bone cysts and are considered by some to be part of the developmental joint disease complex. SCLs in bone were once considered a coincidental finding in horses and not necessarily related to lameness or disease.1,2

Currently they are recognized as a serious cause of lameness that can be difficult to treat.3 They are characterized by radiolucent areas of bone (from several millimeters up to and even larger than 3 cm) often accompanied by a thin, but well-demarcated, sclerotic rim (Fig. 92-1). The center of the SCL is usually filled with a myxomatous tissue with or without fluid that resembles normal or slightly blood-tinged synovial fluid.4 The SCL cavity was thought to be lined with a synovial-like membrane that was responsible for fluid production; however, this membrane cannot be verified in all instances.5

SCLs can be uniloculated or multiloculated and occur usually in the subchondral bone underlying the articular cartilage in a weight-bearing area of the joint.4,6 Occasionally they are also found in the metaphysis or close to the growth plate.4,7

SCLs occurring in the medial femoral condyle of the horse have been classified into three types according to Howard and colleagues.5 Type 1 lesions are 10 mm or less in depth and have a shallow saucer or dome-shaped, concave appearance. Type 2 lesions exceed 10 mm in depth and typically are domed, conical, or spherical. Type 3 lesions

have a flattened or irregular contour, or both. A similar classification system was proposed by Jeffcott and Kold, but lesions were divided into two types: group A corresponds to the type 1 and 2 lesions of Howard and colleagues, and group B includes type 3 lesions as well as those in the proximal part of the tibia.

In the past, SCLs were considered part of the osteochondrosis (OC) complex. However, recently they were shown to be inflammatory in origin. In addition, the location of OC lesions is different from that of SCLs. Normally, OC lesions occur at the transition from the weight-bearing to the non-weight-bearing articular surface, whereas SCLs are found underneath the cartilage in a weight-bearing area of the joint.

ETIOLOGY AND PATHOGENESIS

Many pathologic mechanisms leading to the development of SCL have been proposed. However, only two hypotheses have been supported experimentally in horses.

The first hypothesis is based on a hydraulic theory and was supported by an experiment in which a slit-like lesion created in the articular cartilage led to the development of SCLs over a period of several months. Other coincidental findings of SCLs in experiments using osteochondral grafting procedures support this theory, because SCLs developed at the host-graft interface between the osteochondral transplants and the host bone. These experiments had a common denominator: there was primary cartilage damage followed by secondary intrusion of synovial fluid. The fluid was thought to be responsible for mechanical pressure on the subchondral bone through its hydraulic action during weightbearing.

The second hypothesis evolved around cellular and molecular mechanisms, where inflammation could be demonstrated in tissues and cystic fluid harvested from SCLs in horses. The fibrous tissue harvested from the center of the lesion contained elevated concentrations of the local pro-inflammatory mediator prostaglandin E2 (PGE2), which also was found in high concentration in the cystic fluid. In addition, an up-regulation of mRNA of interleukin 1 (IL-1) and IL-6 was documented in the SCL. Using quantitative real-time polymerase chain reaction (qRT-PCR), an up-regulation of IL-1 could be demonstrated at the periphery and IL-6 at the center of the lesion. Lastly, increased recruitment and activation of osteoclasts could be elicited in vitro when media of cultured fibrous, cystic tissue, and cystic fluid was incubated with osteoclasts isolated from 1-day-old rats (the pit resorption assay). This was attributed to the combined effect of the cytokines IL-1 and IL-6 and the mediator PGE2, which are normally elevated in clinical cases of pathologic bone resorption and inflammation.

Other mechanisms have been suggested in the development of SCL in horses. These include primary subchondral bone damage and secondary collapse of overlying cartilage, disturbances of endochondral ossification, primary intraosseous fibroplasias or metaplasia, herniation or protrusion of synovial membrane through a small fissure in the articular surface, and vascular disturbances. In contrast to the two theories presented earlier, none of these have been supported experimentally.

EPIDEMIOLOGY OF SUBCHONDRAL CYSTIC LESIONS

An extensive literature review involving 703 lesions in 619 horses (84 bilateral) revealed that SCLs occur mainly in the medial femoral condyle (45.8%), followed by the phalanges (26.2%) including the navicular bone (18.5% of all phalanges), carpal bones (7.1%), metacarpal and
metatarsal bones (6%), tibia, radius, talus, proximal sesamoid bones, humerus, patella, scapula, distal tarsal bones, and hemimandible (all less than 5%). Sex distribution revealed that 62% of SCLs occur in males (including 41% stallions and 21% geldings). Thoroughbreds represented the majority of affected animals (39.5%), followed by Quarter Horses (14.1%), Crossbreds (12.2%), Standardbreds (9.9%), Arabian horses (8.5%), and Warmbloods (7.3%), with less than 5% in various other breeds. It seems that Warmbloods were overrepresented with cysts occurring in the phalanges, often in combination with osteoarthritis, mostly in the phalangeal joints.

**CLINICAL SYMPTOMS**

Horses are often presented with lameness in the affected limb with or without joint effusion. Lameness is attributed to increased intracystic or intraosseous pressure, or both. SCLs occur mostly in young horses between the ages of 1 and 3 years, when lameness commonly appears at the onset of training. If SCLs are seen in older horses (Warmbloods), they often are accompanied by osteoarthritis and associated with a poor prognosis. Although the onset of lameness can be acute, the lesions are usually longstanding, having been formed over time.

SCLs usually can be localized using routine lameness examinations followed by standard radiographic views of the affected joints. In rare cases, SCLs cannot be visualized using routine radiographic techniques, and computed tomography has been of great value (Fig. 92-3). In a recent report, a variety of occult lesions in various bones of the tarsus, which were not radiographically visible, were localized using scintigraphy and confirmed with computed tomography. SCLs can also be found unexpectedly during exploratory arthroscopic examination.

Joint communication between the SCL and the overlying joint occurs only in a third of affected animals and can only be visualized during arthroscopic surgery (Fig. 92-4) if the overlying cartilage collapses into the SCL. The cartilage overlying an SCL might be normal except close to the canal, where signs of matrix degradation can be detected (Fig. 92-5). In cases where SCLs are associated with osteoarthritis, signs pertinent to osteoarthritic cartilage lesions are present (see Chapter 83).

**Figure 92-2.** Radiographic view of a subchondral cystic lesion in the distal aspect of the proximal phalanx of a 9-year-old Warmblood gelding. The lesion is accompanied by osteoarthritis of the proximal interphalangeal joint.

**Figure 92-3.** A, Computed tomographic image of a subchondral cystic lesion (SCL) in the metacarpophalangeal joint of a 4-year-old Warmblood mare, which was not clearly apparent on radiographs. B, The postmortem specimens demonstrate that the SCL is not completely formed and that bone was still present within the SCL cavity.

**Figure 92-4.** Postmortem specimen of a femoral condyle demonstrating a communication of a subchondral cystic lesion with the joint, which occurs in only 30% of the cases.
Tissues harvested from SCLs at the time of surgery or necropsy (Fig. 92-6) reveal dense fibrous or myxomatous tissue containing necrotic bone, calcified or mineralized areas, or fibrocartilage in some instances. The cystic wall consists of elongated fibroblasts aligned parallel to collagen bundles, scattered macrophages, and polymorphonuclear cells. Hypervascularity and thickened bone trabeculae can be noticed in the adjacent bone.

**MANAGEMENT OF SUBCHONDRAL CYSTIC LESIONS**

Conservative treatment of SCLs using nonsteroidal anti-inflammatory drugs (NSAIDs), vitamin supplements, and anabolic drugs is not recommended because it is successful in only 33% of cases. Surgical débridement of the lesion with a thorough curettage of the cystic tissue and lining is considered the treatment of choice, because a postoperative soundness up to 74% can be expected. The animal is anesthetized and, depending upon the location of the SCL, the preference of the surgeon, and the approach selected, the patient is positioned in lateral or dorsal recumbency on the surgery table. The surgical site is prepared for aseptic surgery and draped. Surgical débridement is performed either using an intra-articular approach by arthroscopy or a trans-cortical approach.

The arthroscope is introduced into the affected joint using routine technique. The lesion is identified either through the presence of a canal when the SCL has a communication with the joint or by a slight indentation or a "Mercedes star" irregularity. With the help of a hypodermic needle, the location for the instrument portal is identified. A no. 11 scalpel is used to make a small incision through the skin and into the joint along the needle path. The blunt...
obturator is used to identify the cyst either by advancing it through the small articular cartilage opening or by pushing it through the soft, slightly movable cartilage into the cyst.

A rongeur can be used to remove the articular cartilage overlying the SCL. A motorized cartilage resector also may be used to remove the cartilage, but it is often cumbersome and time consuming, because the cartilage is often too thick and pliable to be easily removed this way. Once all the cartilage not supported by underlying bone is removed, the contents of the cyst are evacuated with the help of a curet. Osteostixis of the adjacent bone is not recommended because it can lead to expansion of the cyst.1,28

The addition of intralesional corticosteroids at the time of surgery has been reported to improve the outcome considerably.29 Packing the lesion with autogenous grafts also has been recommended.30,31 However, a study comparing healing of surgically created subchondral defects filled with compacted cancellous bone grafts compared to unfilled defects revealed no difference in the healing patterns after 6 months.32 This type of management is not used anymore. Closure of the arthroscopy portals is routine.

Some SCLs are not accessible through an articular approach and have to be débrided transosseously. Careful preplanning of the surgery is necessary.

The skin incision over the selected location is advanced down to the bone. Under fluoroscopic control, a 2.5-mm pilot hole is drilled across the bone into the cyst. If no fluoroscope is available, frequent radiographic images are needed to verify the correct drill direction. If the SCL communicates with the joint, distending it with saline solution may allow backflow through the drill hole once the drill penetrates the SCL. Once placement of the drill tip into the SCL has been verified, the drill hole is enlarged with a 5.5-mm drill bit so that it will accept a curet.

The contents of the cyst are evacuated, taking care to not traumatize the articular cartilage. This can be verified through fluoroscopy or radiography. The cystic lesion and drill hole can be filled with a cancellous bone graft. Other materials that have been used to successfully treat SCL include tricalcium phosphate granules (Fig. 92-7), hydraulic injectable biodegradable cements (Fig. 92-8), and composites of hydrogels and growth factors25,26 (Fig. 92-9). Closure of the incision is routine.

Postoperative management of both treatment techniques is the same as for any arthroscopic surgical intervention. The healing of treated SCL normally is slow and can take several months to years if just surgical débridement is used, but the approach using bone replacements seems to enhance bone healing of the curetted lesion and thus to shorten healing time considerably. Younger horses have a better prognosis for complete recovery compared to older horses. This is especially true if SCLs are associated with osteoarthritis in older patients, and a cautious prognosis should be given.

Figure 92-7. A, Preoperative dorsopalmar radiographic view of an SCL in the distal aspect of the proximal phalanx. The cyst was curetted and filled with tricalcium phosphate granules through a transcortical approach. B, Dorsopalmar radiographic view 2 years later. Complete healing has occurred.
Figure 92-8. A, Dorsopalmar radiographic view of the distal MCIII depicting a cystic lesion, which involved the entire medial condyle. B, The defect was approached using an 8-mm diameter drill bit and filled with injectable biodegradable bone cement (chronOsInject: Synthes Inc, Solothurn, Switzerland). C, The 12-month follow-up radiograph shows satisfactory healing of the defect. The animal was pain free at a walk and trot.

Figure 92-9. A, Immediate postoperative dorsopalmar (left) and lateromedial (right) radiographic views of a young horse with a subchondral cystic lesion (SCL) in the distal proximal phalanx. The cyst was enucleated through a transcortical approach and was treated with fibrin-based hydrogel and PTH1-34. B, Four-month follow-up radiographs of the horse seen in A. Note that bone density has increased considerably and the SCL is hardly visible on radiographs.

CHAPTER 93

Foot
Anton E. Fürst
Christophorus J. Lischer

A multitude of disorders affect the equine foot. Once the problem is diagnosed, a decision has to be made whether to treat it conservatively or surgically. In some conditions, surgery serves as an option after conservative management has failed to bring about an improvement. For other problems, surgical intervention is the best or even the only treatment option. In this chapter, frequently encountered disorders of the foot managed by surgery are discussed.

DISORDERS OF THE HOOF CAPSULE

Often, changes in the hoof horn quality are noticed that jeopardize the use of the horse for competition or pleasure riding.1,2 The old saying “no hoof, no horse” still holds true even nowadays with all the sophisticated treatment possibilities available in veterinary medicine, which clearly affirms the importance healthy hooves have for the everyday use of horses. Therefore, special attention should be given to the feet not only during lameness evaluations but also during prepurchase examinations, where the clinician is asked to provide the potential new owner of the horse with a statement regarding the future usefulness of the horse for its intended purpose.

CHAPTER 93

Foot
Anton E. Fürst
Christophorus J. Lischer

A multitude of disorders affect the equine foot. Once the problem is diagnosed, a decision has to be made whether to treat it conservatively or surgically. In some conditions, surgery serves as an option after conservative management has failed to bring about an improvement. For other problems, surgical intervention is the best or even the only treatment option. In this chapter, frequently encountered disorders of the foot managed by surgery are discussed.

DISORDERS OF THE HOOF CAPSULE

Often, changes in the hoof horn quality are noticed that jeopardize the use of the horse for competition or pleasure riding. The old saying “no hoof, no horse” still holds true even nowadays with all the sophisticated treatment possibilities available in veterinary medicine, which clearly affirms the importance healthy hooves have for the everyday use of horses. Therefore, special attention should be given to the feet not only during lameness evaluations but also during prepurchase examinations, where the clinician is asked to provide the potential new owner of the horse with a statement regarding the future usefulness of the horse for its intended purpose.
Many hoof problems have a number of predisposing causes, such as faulty feeding regimens, including vitamin and mineral deficiencies, as well as excessive and uncontrolled work load, especially on hard and dry ground. Poor hygiene and inadequate hoof care propagate hoof problems because urine and manure weaken or in some cases destroy horn integrity. Trimming and shoeing practices can exacerbate problems with hooves that initially had minimal changes in horn quality. The hoof capsule can be damaged by different external insults. Last but not least, some horses are born with hooves of decreased quality, possibly triggered by genetic factors. These animals may be predisposed to hoof problems despite good stall hygiene, excellent feeding practices, and adequate exercise. Supplementation with biotin improves horn quality over time in some horses.\textsuperscript{1,2}

**Thrush**

*Etiology and Diagnosis*

*Thrush* refers to infection that leads to necrotic processes in the frog area, especially in the central and lateral sulci.\textsuperscript{3} The sulci become soft and slimy and emit a characteristic foul-smelling odor commonly recognized with this disorder. Horn damage can progress to involve the sensitive lamina; then it is referred to as pododermatitis. As a result of the soft nature of the altered horn, foreign body penetration is more likely.

Manure and urine accumulation in the foot dissolve horn in the frog area in association with bacteria and fungi. Therefore, this condition is seen in conjunction with poor stall hygiene and neglected hoof care. However, a contracted hoof and lack of exercise can also predispose a hoof to thrush. Different bacteria and fungi have been shown to colonize the horn of the frog and eventually destroy it.\textsuperscript{4-6}

*Treatment and Aftercare*

Meticulous hoof care and good stall hygiene are an important part of resolving this condition along with local treatment of the altered horn in the frog area. Box stalls should be thoroughly cleaned at regular intervals, and all urine-soaked straw or wood shavings should be removed. The sulci of the frog need to be cleaned twice daily to remove any manure packed into the hoof sole.

All damaged horn is removed, which effectively reduces bacteria and fungi colonization and provides better contact of locally applied medications to the affected tissues (Fig. 93-1). After removing the diseased horn, the sulci are cleaned with a disinfecting solution.\textsuperscript{7} In cases where the sensitive lamina is involved, a protective bandage containing sponges soaked in povidone-iodine (Betadine) should be applied for a few days. Subsequently, the sulci are treated with solutions possessing disinfectant, drying, and hardening properties.\textsuperscript{7} In most cases, solutions containing formalin in one form or another are used. These solutions are applied to gauze sponges or small cotton balls and pushed into the affected sulci.

The majority of thrush medication is toxic to epithelium, and therefore must be applied with utmost care, especially in the presence of severe horn damage and sensitive lamina. It is better to initiate treatment with povidone-iodine-soaked sponges and proceed to stronger medications once a thin horn layer has grown over the defect.

*Prognosis*

Horses suffering from thrush are predisposed to acquiring the problem again, mainly when the inciting causes of inadequate stall hygiene and neglect in hoof care and exercise have not been resolved. Therefore, complete resolution of the problem is possible only if good hygiene is maintained for the rest of the horse’s life.

**White Line Disease**

*Etiology and Diagnosis*

*White line disease* refers to deterioration of the white line of the hoof capsule, resulting in the loss of the bond between the hoof wall and the sole. White line disease is incited through the presence of poor-quality horn, which allows the colonization of different bacteria and fungi.\textsuperscript{8} These microorganisms are not able to grow in normal horn of the white line. They are more commonly encountered in geographic regions with a warm and humid climate.

Once the hoof wall begins to separate from the sole, the hoof wall is exposed to increased tensional forces, which leads to the development of inflammatory processes in the sensitive lamina; lameness is the result. Additionally, the
selective placement of hoof nails into the white line is jeopardized, preventing solid attachment of horseshoes to the foot. If the necrotic processes extend farther proximally, entire parts of the hoof wall may be undermined and eventually form a hollow wall.

**Treatment and Aftercare**

Treatment consists of meticulous stall hygiene and local management of the affected hooves. All the altered and necrotic horn must be removed and the defects treated with solutions to destroy the remaining bacteria and fungi. The solutions used are the same ones used to manage thrush (see earlier). The débridement might need to include hoof wall resection (see later).

**Hollow or Loose Hoof Wall**

**Etiology and Diagnosis**

A hollow or loose hoof wall develops when there is a disruption of the most axial layers of the hoof wall, near the sensitive lamina (Fig. 93-2). A loose, hollow wall can develop from an extension of white line disease. In other cases, breeding into the hoof wall seems to be the inciting cause. Chronic tearing as a result of continuous excessive use can lead to a separation within the hoof wall. As an example, 50 years ago, hollow walls were commonly diagnosed in pulling horses. Soil, bacteria, and fungi can get access to the dead space between the hoof wall layers and induce a local infection.

As long as no infection is present and the sensitive lamina is not involved, it is possible to apply horseshoes to the foot. However, there is always a risk that the hollow wall will continue to extend proximally, which makes treatment more difficult. Therefore, effective treatment of a hollow wall should be initiated early in the course of events, especially in the presence of an infection.

**Treatment and Aftercare**

Successful therapy can be achieved only if all diseased, necrotic horn is removed. The remaining hoof defect must be treated with solutions effective against bacteria and fungi, using moist hoof bandages. Depending on the extent of the hollow wall, a considerable amount of horn may have to be removed (Fig. 93-3, A), which can result in a prolonged convalescent period. Treatment can last several months and the problem must be completely resolved before the horse can be ridden again.

Several artificial hoof products are on the market that allow the lost hoof wall to be replaced effectively. Products such as Keralit (Scheule GmbH, Kirchheim, Germany) or Sigafoos (Horsetec AG, Zeihen, Switzerland) have characteristics similar to normal hoof wall in respect to stability and flexibility, and they are ideally suited to replace horn defects. The artificial horn products contain two components that are mixed together and develop into a sticky, easily moldable mass. Once molded into the clean and dry hoof wall defect, artificial horn is subsequently shaped to the contours of the hoof wall (see Fig. 93-3, B). Within a few minutes, the material hardens into hornlike material. The hoof replacement material can be reinforced with fiberglass webbing for additional strength.

The advantages of these products are that the susceptible laminae are covered with a durable protective layer, which increases the stability of the entire hoof wall. The artificial hoof wall also allows the placement of a horseshoe (see Fig. 93-3, C).

As a result of the continuous growth in the rest of the hoof wall, the artificial hoof wall has to be replaced repeatedly. There is a potential danger that an infection can...
develop under the artificial horn, necessitating its immediate removal. Therefore, careful monitoring of the healing process is required until the defect is completely replaced by new hoof wall, which will grow down from the coronary band.

**Hoof Wall Cracks**

**Etiology**

A hoof wall crack represents a longitudinal disruption of the hoof wall parallel to the horn tubules and lamellae. It can involve the entire length of the hoof wall, the proximal hoof wall near the coronary band only, or the distal hoof wall only (Fig. 93-4). The crack can penetrate the superficial layers only or can extend into the sensitive lamina. These cracks are called *deep* or *perforating hoof cracks*; the perforating hoof cracks result in inflammation and lameness (Fig. 93-5). Horizontally oriented hoof defects, at an angle parallel to the coronary band, are called *hoof crevices*, but they have the same etiology and treatment as hoof cracks.

The causes of the hoof cracks are diverse. Poor horn quality or a horn wall that is too thin are predisposing factors. Abnormal hoof angles can produce significant tension gradients within the hoof wall, which develop into cracks.12

**DISTAL HOOF WALL CRACKS**

Poor horn quality associated with excessive workload and poor hoof hygiene can lead to development of hoof cracks at the distal hoof wall (see Fig 93-5). Usually, these cracks are superficial initially and do not cause lameness unless they extend and develop into a perforating crack. A horizontal groove may be cut at the most proximal aspect of the crack, and the foot should be trimmed very short to prevent proximal and deep extension. If these management practices do not stop the progression of the crack, then more aggressive surgical techniques will be required (see later).

**PROXIMAL HOOF WALL CRACKS**

Proximal hoof wall cracks develop as a result of local trauma, inflammation, or scar tissue near the coronary band. Because of such damage, horn of poor quality is formed, facilitating the development of a hoof wall crack.

---

*Figure 93-4. Different locations of hoof wall cracks. a, Dorsal crack extending over the entire length of the hoof wall. b, Proximal lateral hoof wall crack. c, Distal lateral hoof wall crack.*

*Figure 93-5. Hoof wall with a cut-away area, showing cracks penetrating to different depths. a, Superficial hoof wall crack. b, A deep or perforating hoof wall crack involving the sensitive lamina.*
These cracks slowly extend distally with concomitant horn growth.

**HOOF CRACKS INVOLVING THE ENTIRE LENGTH OF THE HOOF WALL**

There are many etiologies of hoof cracks along the entire hoof wall, aside from local trauma to the coronary band. Most likely, tension gradients inside the hoof wall combined with extensive use and poor horn quality are major predisposing factors in their development. Often such hoof cracks are found in hooves with excessively long sidewalls (Fig. 93-6, A and B). Hoof cracks are more commonly seen on the medial hoof wall than on the lateral wall.

Uneven heels and displaced bulbs of the heel are predisposing factors. Hoof wall cracks can also be caused by faulty shoeing practices, such as shoes that are too short, branches that are too narrow or side clips applied too far back, uneven hoof soles, and hoof nails inserted too far caudally. When unphysiologic conditions such as these are present for several months, poor-quality horn can grow, predisposing the hoof wall to crack formation. The combination of long shoeing intervals and excessive work foster hoof crack development.13

**Diagnosis**

Most of the time the diagnosis is made on close visual inspection of the hoof. The deeper layers of the crack often are impacted with dirt and manure. Lameness is a prominent feature of deep or perforating hoof wall cracks. Conversely, superficial horn cracks are not associated with lameness and many do not require treatment. Nevertheless, there is always a risk that a superficial crack will extend into one that eventually initiates an inflammatory process.

**Treatment and Aftercare**

Because hoof cracks are encountered often and have been a common problem for hundreds of years, many treatment methods are described. However, although many methods and techniques exist, successful management of hoof cracks demands close cooperation among the clinician, the farrier, and the owner.

The type of treatment selected depends on the location and depth of the crack, and the duration of treatment can take from a few days to several weeks or even months. The first line of attack involves improvement of hoof care and shoeing.14 The repair of the hoof crack without initial débridement can reduce the movement of the two sides relative to each other, effectively protecting the underlying sensitive laminae. In these instances, lameness will be attenuated. In rare cases, the crack can heal completely, allowing regrowth of normal horn from the coronary band distad. In most cases, however, more-involved techniques are necessary to bring about healing of the defect, especially if the crack is accompanied by infection and lameness.

First, the conditions of the shoes have to be assessed, correcting present abnormalities such as uneven heels and abnormal hoof angles. The old shoe is removed and the hoof is properly trimmed. By cutting the heels short, local pressure in the hoof wall can be partially reduced.

Subsequently, the horn adjacent to the crack is carefully removed with a Dremel tool15 (Fig. 93-7). All altered horn down to the sensitive lamina is removed, taking special care to establish smooth transitions toward the sides. Once completely cleaned, the defect is covered with gauze sponges, and a hoof bandage is applied. The foot is shod with a bar shoe, and the sole is filled with silicone and covered with a metal plate. This reduces pressure in the heel region, which is especially beneficial if the crack is located in this area. In some cases, the coronary band immediately proximal to the crack is displaced dorsally. Trimming the hoof wall short just below this crack reduces the continuous movement at the coronary band and leads to the production of better-quality horn.

Last, a fixation device should be applied to the crack. If the crack was débrided down to the sensitive lamina, fixation has to be delayed until a subtle layer of horn covers the defect.

An effective repair unites the two separated hoof parts and reduces individual movements at the transition to the normal horn proximally at the level of the coronary band.

---

**Figure 93-6.**

A, A hoof with a long and steep inside wall and uneven heels containing a hoof crack.

B, Contracted hoof with a distorted coronary band and a hoof crack.
There are a variety of methods that can be used to repair a hoof crack (Fig. 93-8). The introduction of the two-component hoof replacement materials mentioned earlier have significantly improved the effectiveness of hoof crack repair.11 These materials provide a natural covering of the crack with a material having properties similar to the normal hoof wall. These materials cure with an exothermic reaction. Therefore, it is important that at least a thin layer of horn be present to protect the sensitive lamina. It is even possible to install a drainage system underneath the artificial horn.

The hoof wall must be covered over almost its entire length to prevent a recurrence of a crack (Fig. 93-9). Poor horn quality might dictate that a covering of artificial horn be maintained for several months. New horn growing from the coronary band eventually completely replaces the repaired hoof wall.

Immediately after the repair, the patient should be kept in a stall for a few days before gradually being returned to exercise. Depending on the quantity and quality of new horn production, the patient may be lightly used after 4 to 8 weeks.

Prognosis
The prognosis for a successful treatment of a hoof crack is good to guarded. Often, the crack recurs, especially if the predisposing factors are not abolished (Fig. 93-10). Because the properties of the horn vary with the location on the hoof,16-18 the prognosis varies as well.

Keratoma
Etiology
A keratoma represents a columnar thickening of the hoof horn that extends toward the inside of the hoof (Fig. 93-11). Because it is rare, the disorder is often overlooked. In addition to the classic keratoma, with its cylindrical appearance and protrusion parallel to the horn tubules, a spherical form of keratoma has been described that can develop anywhere in the hoof capsule.19

Most keratomas are found in the dorsal aspect of the wall. A local inflammation reaction or trauma at the transition of the new horn produced at the coronary band and hoof wall is the most likely inciting cause. This results in the formation of scar tissue in that location, which gradually grows distal as new horn is produced.

A hoof abscess also can lead to the development of a keratoma. Because of the expansiveness of the keratoma, unphysiologic pressures are exerted on the sensitive laminae and the distal phalanx, leading to inflammation and lysis of
the underlying distal phalanx. The keratoma consists of poor quality horn, which decays early, allowing bacteria and fungi access to the inside of the hoof wall. Therefore, keratomas are often associated with local hoof wall infections and are the reason horses are presented to veterinarians. If a patient is presented with a chronic recurrent hoof abscess, it is prudent to assume a keratoma is the actual cause of the problem.

**Diagnosis**

Careful inspection of the sole is important for the diagnosis. Trimming and cleaning of the sole surface is necessary to recognize the abnormal configuration of the white line. Typically, the lamellar horn of the white line is replaced by tubular horn and scar tissue (Fig. 93-12 A). The pathologic tissue displaces the white line toward the sole. In advanced cases, a circular lytic area of the distal phalanx can be

**Figure 93-10.** An inadequate repair with artificial horn led to recurrence, with the crack extending partially across the artificial horn.

**Figure 93-11.** Keratoma in the hoof shell. **A,** Representation from the inside. **B,** First manifestation at the median of the white line (arrow).

**Figure 93-12.** **A,** Clinical case with a local chronic infection in the sole. **B,** Radiograph of the same patient showing a lytic area in the distal phalanx extending up along the hoof wall (surrounding white arrows), which is typical of a keratoma.
recognized radiographically (see Fig. 93-12 B). This area should not be mistaken for the naturally occurring crena at the dorsal aspect of the distal margin of the distal phalanx. Often, a sclerotic border delineates the lytic area (see Fig. 93-12 B).

**Treatment and Aftercare**

In selected cases, it is possible to temporarily abolish the signs of a keratoma with the help of conservative management. However, even with meticulous hoof care and good hygiene it is not always possible to prevent the formation of a hoof abscess. Therefore, an early surgical approach toward solving the problem is advised. For successful resolution, two main principles must be observed: the keratoma must be completely removed up to its origin, and support has to be given to the hoof wall.

The timing of the surgery depends to a certain extent on the condition of the patient and the intentions of the owner. The main dilemma is whether to first manage the inflammatory processes medically and remove the keratoma once it has resolved, or to immediately enucleate the structure. The choice should be based on the amount of pain shown by the patient; early intervention may be indicated in very lame patients to avoid laminitis in the contralateral foot. Aside from the altered horn, the altered sensitive laminae also must be removed. The hoof wall defect may be filled with artificial horn as soon as the sensitive lamina is healed. Additionally, a special shoe with large clips placed on either side of the defect should be applied to the foot.

The surgical intervention is performed in two steps, with a tourniquet applied above the foot. First, as much horn as possible is removed with the horse standing until the Dremel tool has to be exchanged for the scalpel and curets. The second stage of the procedure is carried out under aseptic conditions, and the altered lamina and the entire keratoma are removed in toto. This procedure also may be carried out on the standing horse if ring block at the level of the metacarpophalangeal joint is used. The advantages of performing the removal under general anesthesia are the more comfortable position for the surgeon and immobility of the patient. It is of utmost importance to remove all pathologically altered tissue in addition to the altered hoof horn. The keratoma usually has a characteristically round appearance at its origin.

At the end of the procedure, an aseptic pressure bandage is applied to the phalangeal region, and the tourniquet is removed. The bandage is changed at 3- to 4-day intervals under aseptic conditions. As soon as the bone is covered by granulation tissue, a medication plate shoe is applied. The hoof wall should be preserved to provide stability to the hoof capsule.

The horse remains confined to a box stall for 4 to 6 weeks, during which the wound is treated routinely with dressings. After this time, a new shoe is applied. Depending on the healing process, different avenues may be taken. If healing progresses normally, the defect may be filled with artificial horn and the patient subjected to light walking exercise and, after approximately 4 months, light riding work. If signs of infection recur, all affected tissues have to be removed and the process of postoperative management started again.

**Prognosis**

With surgical treatment, a significantly better prognosis can be given (83% success rate) compared to conservative management, where an approximate success rate of 43% has been published.

**SEPTIC AND ASEPTIC DISORDERS OF THE SOFT TISSUES**

**Acute Hoof Abscesses**

**Etiology**

"Hoof abscesses have 1000 faces." Hoof abscesses are among the most frequently diagnosed causes of lameness seen in equine practice. It is interesting to realize how many symptoms a hoof abscess may generate. It is therefore not surprising that this problem is occasionally misdiagnosed.

Hoof abscesses develop in the unshod horse—often foals—as well as in shod horses. No breed or age predispositions are known. After penetration of bacteria across the hoof wall, infection develops in the region of the sensitive lamina, which includes the accumulation of purulent material within the hoof capsule (Fig. 93-13). Because the hoof capsule provides a solid external shield, increased pressure builds up inside, leading to severe, non–weight-bearing pain. Box 93-1 lists some possible etiologies for a hoof abscess. A sole bruise is the most likely to occur.

![Figure 93-13. Location of a typical hoof abscess at the tip of the foot (above) and at the side (below).](image-url)
Diagnosis

The cardinal symptom is a sudden severe lameness, which might be described as "fracture lameness," resulting in the horse's being admitted to the clinic as a fracture patient. The horse might be febrile and have increased warmth of the foot, with strongly pulsating distal palmar and plantar arteries. A generalized swelling of the distal limb might be noticed, which can lead to the erroneous diagnosis of septic tenosynovitis or other similar conditions. Local application of pressure through the hoof tester generally elicits a marked positive response. Local perineural anesthetic blocks (deep palmar anesthesia, middle palmar/plantar anesthesia) aid in localizing the problem, allowing subsequent pain-free treatment. Complete blood count (CBC) and blood chemistry analyses are usually unrewarding, but in some cases radiography supports the tentative diagnosis of hoof abscess.

Treatment and Aftercare

If a hoof abscess is suspected, the shoe should be removed and each nail closely examined for wetness and odor. Subsequently, the exact location of the abscess is established with the help of the hoof testers. Location with the hoof tester can be difficult in the presence of thick and hard sole horn. In such a case, it might be necessary to apply a povidone-iodine or creosote bandage for overnight, which results in softening of the hoof horn, permitting localization of the abscess and subsequent drainage.

All the undermined and necrotic horn is carefully removed, piece by piece, until a smooth transition is achieved toward the surrounding normal sole (Fig. 93-14). Subsequently, the infected area is cleaned with iodine solution or $\text{H}_2\text{O}_2$ and covered with a povidone-iodine-soaked gauze sponge and a hoof bandage. The bandage is changed after 2 to 3 days under aseptic conditions. At that time, the defect is closely examined and any additional undermined sole is carefully removed. As soon as the site is dry, the horse can be reshod. It is prudent to cover the site with a leather or synthetic pad.

If the abscess is not managed properly or in a timely fashion, it can break through at the coronary band (Fig. 93-15) or extend deeper into the foot and involve the distal phalanx. In these cases, the draining tract has to be flushed daily with diluted povidone-iodine solution from the coronary band distad (Fig. 93-16). Distal exit of the flushing solution is important. The foot must be kept in a bandage until drainage has stopped.

**BOX 93-1. Possible Etiologies for a Hoof Abscess**

- Placement of hoof nail too close to the sensitive lamina, allowing bacteria along the nail to induce an infection in close proximity to the sensitive lamina
- Insertion of a hoof nail into the sensitive lamina, resulting in an infection
- Small pointed rocks penetrating the solar horn
- Any penetrating foreign object, such as a street nail
- Any sole bruise, which creates a blood culture medium for the growth of bacteria that enter the tubules in the horn normally

---

**Figure 93-14.** A subsolar abscess was opened; the purulent material is shown draining (arrow).

**Figure 93-15.** Delayed diagnosis or delayed treatment can lead to the abscess breaking out at the coronary band.

**Figure 93-16.** The abscess is flushed daily from the coronary band toward the sole with diluted povidone-iodine (Betadine) solution.
Administration of nonsteroidal anti-inflammatory drugs (NSAIDs; e.g., phenylbutazone) is indicated. Antimicrobials also are indicated, especially when bone involvement is suspected. Generally a good prognosis can be given, even though advanced abscesses can take weeks to heal completely.22

**Chronic Hoof Abscesses**

**Etiology**

On rare occasions, a hoof abscess might not be diagnosed right away, especially if the horse has been treated with pain-relieving medications for a period of time. The clinical symptoms are more or less effectively masked, preventing recognition of the problem and its treatment. Also, administration of NSAIDs prevents the abscess from maturing and can permit the microorganisms to invade other tissues within the foot. The abscess can extend into the foot along three avenues: along the dorsal and lateral hoof wall in a proximal direction, eventually breaking out at the coronary band (see Fig. 93-15); along the sole, potentially undermining it completely; or along the distal phalanx, resulting in septic pedal osteitis.23,24

**Diagnosis**

Physical examination of the foot might reveal a draining tract. A thorough radiographic evaluation, with or without a probe positioned in the draining tract, often helps make the diagnosis, because at this point radiographic changes usually are visible on the distal phalanx. Lytic changes can develop as a result of a chronic abscess as well as after aseptic local inflammation.

**Treatment and Aftercare**

The abscess needs to be opened and all the undermined sole removed until normal horn is encountered.23,24 If the infection spreads out along the side wall, all the undermined wall must be carefully removed, again until normal wall is encountered. If the distal phalanx is involved, all the affected bone must be curetted. The treatment of a chronic abscess can take several weeks to months, especially if a substantial amount of hoof wall needs to be resected.

**Aseptic Pododermatitis**

**Etiology**

Aseptic pododermatitis is a severe bruising of the laminae and horn tissues of the foot and is a common cause of lameness in horses. Often this problem is not recognized immediately, and the concomitant lameness is attributed to navicular disease or osteoarthritis of the distal interphalangeal joint. There are many possible causes for this problem: poor shoeing technique, excessive use of the horse under difficult conditions such as hard, uneven ground, and frequent kicking against the stall wall.

**Diagnosis**

The symptoms are typical but not very specific, leading occasionally to a misdiagnosis (Fig. 93-17). The hoof is slightly warmer than normal and a positive pain reaction can be elicited with the hoof testers. Pulsation of the palmar arteries is usually increased. Palmar digital nerve anesthesia usually relieves the lameness. Radiography helps to differentiate the problem from a fracture in this region. Keratoma is part of the differential diagnosis in cases of chronic persistent pododermatitis.

**Treatment and Aftercare**

Management of this disorder is directed at removing the actual cause. In most cases, the shoe must be removed. Application of creosote bandages for three or more days is very effective. These bandages are followed by dry bandages for a prolonged period. Some patients require NSAIDs because of persistent pain. Some hand-walking on soft ground is optional, and after 7 to 10 days the horse is reshod.

**TRAUMATIC INJURIES**

**Puncture Wounds**

**Etiology**

"Nail prick" refers to injury caused by inadvertently driving a nail through the sole and sensitive laminae during shoeing. "Street nail" refers to puncture of the solar surface of the hoof by nails or other sharp objects such as screws. A hoof is "nail bound" when a horseshoe nail is driven too deep into the horn, causing excessive pressure on the corium. All three types of injuries usually result in pain, inflammation, and infection.

Although puncture wounds of the sole can appear small (Fig. 93-18), they are often deep and can have disastrous
effects when structures such as the distal phalanx, distal sesamoid bone, distal interphalangeal joint, navicular bursa, deep digital flexor (DDF) tendon, or tendon sheath are penetrated (Fig. 93-19). The penetrating object is usually contaminated with soil, rust, or manure, which can lead to serious infection. The superficial wound in the sole usually seals quickly, leaving no area for drainage. The anaerobic environment created favors the growth of *Clostridium tetani*, the microorganism causing tetanus.

Depending on the location and depth of the puncture wound, various structures can be affected (see Fig. 93-19). Deep puncture wounds are extremely serious and difficult to treat; affected horses are often referred to specialized clinics for surgical therapy. For these reasons, deep puncture wounds must be treated as an emergency to prevent the infection of bones, joints, and tendon sheaths.

**Diagnosis**

Horses usually have a moderate to severe supporting-leg lameness, often pointing the affected toe. The hoof is warmer than normal, and there is increased pulsation of the digital arteries. The horse might have a fever. Examination with hoof testers usually elicits severe pain. In horses with severe acute lameness, the hoof must be thoroughly cleaned and examined for a foreign body or puncture wound (see Fig. 93-18).

**Treatment and Aftercare**

The nail or foreign body should be promptly removed. However, it is imperative that the depth and direction of the tract be noted and the point of entry marked on the sole or recorded on paper, because it will rapidly become inapparent. The point of entry is cleaned, and the entire hoof is bandaged.

Based on the location, direction, and depth of the injury, the horse may be treated on site or referred to a clinic. When there is suspicion of injury to deeper structures, such as the navicular bursa, distal interphalangeal joint, or the DDF tendon sheath, the horse must be referred immediately for surgical treatment. Broad-spectrum antibiotics are started, and tetanus antitoxin and toxoid are administered.

**TREATMENT IN A CLINIC**

A thorough clinical examination is carried out, after which local anesthesia is administered. The shoe is removed and the entire hoof is trimmed (see Fig. 93-18). The decision to pursue further treatment is based on the results of clinical examination and radiography. The puncture tract is carefully cleaned and disinfected. A sterile metal probe is inserted into the puncture tract, and the hoof is radiographed in two planes (Fig. 93-20 A). Placing a needle into the navicular bursa using aseptic technique and injecting a contrast medium can enhance the diagnosis (see Fig. 93-20, B). A 20-gauge needle is placed in the distal interphalangeal joint and synovial fluid is collected into an EDTA tube. Approximately 10 mL of contrast medium is injected into the joint. After a few minutes, the hoof is radiographed again to determine whether the contrast medium is exiting through the puncture tract. The same procedure is repeated for the DDF tendon sheath.

**Surgical débridement and treatment of puncture wounds**

Surgical débridement of puncture wounds is usually performed with the horse under general anesthesia. This
procedure entails two parts: initial débridement of the sole followed by aseptic treatment of the hoof (Fig. 93-21). With the horse sedated and standing, the hoof is cleaned and the horn around the puncture tract is carefully removed down to a thin layer of horn that can be cut with a scalpel blade. The hair from the hoof to the fetlock joint is clipped. The prepared area is cleaned with chlorhexidine scrub (Hibiscrub) and covered with a bandage.

The horse is positioned in lateral recumbency under general anesthesia and a tourniquet is applied. Occasionally, it is necessary to remove additional horn at this time. All affected structures around the puncture tract are excised. The horn around the tract is removed in an area measuring approximately 3 by 3 cm. The corium and subcutis are then removed and the underlying structures are exposed. When the foreign body has penetrated the DDF tendon, a 1.5 by 1.5 cm area of the tendon is resected (Fig. 93-22). Curettage is necessary if the foreign body penetrates the distal phalanx or the distal sesamoid bone (Fig. 93-23). With perforation of the impar ligament and penetration of the distal interphalangeal joint, the ligament must be resected and the joint lavaged. The flexor tendon sheath requires lavage when it is involved.

The affected synovial structures are lavaged with lactated Ringer’s solution to which antibiotics have been added. A pressure bandage is applied, followed by a hoof bandage and a wedge under the heel. Regional intravenous perfusion with an antibiotic is recommended.

An arthroscopic technique has been developed to lavage and treat a deep puncture wound that penetrates the navicular bursa or distal interphalangeal joint (Fig. 93-24). This technique has good results and permits a less-invasive approach to the penetrated structures, because débridement is carried out under endoscopic guidance. Also, the area is under constant lavage during treatment, decreasing surgery time.

Depending on the severity of the injury, lavage may be repeated once or twice with the horse under general anesthesia. Afterward, with the horse standing and sedated, the bandage is changed under aseptic conditions. Systemic antibiotics and anti-inflammatory drugs are administered for at least 2 weeks. After a certain period of time, a medication-plate shoe can be applied (Fig. 93-25).

Prognosis

The prognosis for puncture wounds of the sole is generally guarded. Horses that receive prompt surgical treatment and have few deep structures affected have the best prognosis. Injury to the distal sesamoid bone can eventually result in adhesions between the bone and the DDF tendon, necessitating neurectomy. Bursoscopic treatment can lessen the development of these types of morbidity.

Scalping Injuries

Etiology

Coronary band (Fig. 93-26) and heel injuries occur at the transition between the skin and hoof capsule. They are usually caused by overreaching, where one foot treads on the coronary band or heel of another foot. Heel calks on
shoes can result in very deep injuries and for this reason should always be removed before trailering.

**Diagnosis**

These injuries are usually quite painful in the acute stages and can cause severe lameness. Inadequate treatment can lead to infection within the hoof capsule. There is also a risk of permanent damage to the horn-producing cells, resulting in abnormalities of hoof growth such as cracks and ridges.

**Treatment and Aftercare**

The damaged horn should be removed to allow drainage of wound secretions. Heavy scissors or a hoof knife are ideal for this. The wound is then cleaned with a mild disinfectant solution and bandaged.

**Other Hoof Lacerations**

Injuries to the hoof capsule are relatively common. Trauma to the corium usually results in marked hemorrhage and severe pain. This type of injury is particularly problematic when the coronary corium is involved; damage to the horn-producing cells results in the production of poor-quality horn. A pressure bandage is applied to injuries that are bleeding severely. The bandage is changed daily until a stable and healthy layer of horn is formed.

**DEGENERATIVE AND NEOPLASTIC DISEASES OF THE FOOT**

**Canker**

**Etiology**

Canker used to be a common disease when draft horses were used for work. Therefore, detailed descriptions can be found in older textbooks. Canker of the frog represents abnormal horn proliferation in the frog region and is rarely seen in other areas of the hoof (Fig. 93-27). It is not a true neoplasm but rather a chronic inflammatory reaction characterized by massive parakeratosis. There is hypertrophy of the sensitive lamina and degeneration of the superficial horn and corium. Canker can spread from the frog to the adjacent sole and even involve the hoof wall.

This disease is slowly progressive and spreads to adjacent structures over the course of months. In some horses, the skin adjacent to the hoof capsule is affected. The skin near
the coronary band is reddened, the hair grows in all directions, and the area is painful when palpated. In rare cases, the horn of the chestnuts is affected.

The cause of canker is not known, although unsanitary stall conditions appear to be a predisposing factor. Long-standing thrush is thought to result in canker formation, because it causes the original degeneration of the horn cells. Horses that are kept in moist and warm stalls with urin-soaked bedding often suffer from canker. Also, there seems to be a breed predilection; draft horses are most commonly affected, but the disease is also seen in Thoroughbreds, Standardbreds, ponies, and even donkeys. A genetic predisposition for this condition has been suggested. Young horses rarely have canker.

The hind hooves are more often affected than front hooves, and one or more hooves may be involved. Bacteriologic examination of affected tissue usually reveals gram-negative anaerobic bacteria. Although many micro-organisms can be isolated, anaerobic bacteria seem to be most important in this disease.
A differential diagnosis must include advanced thrush and fungal infection of the coronary band.

**Diagnosis**

Horn of rubber-like consistency that breaks easily on the surface is characteristic of canker. The horn produced by the epidermal cells affected by canker is soft, greasy, and friable. Cauliflower-like growths that are not cornified at the surface but covered with a greasy, grayish-white material are typical. These hypertrophic horn growths have a foul odor somewhat reminiscent of an abscessed tooth. Once traumatized, the area bleeds profusely. The poor horn quality can result in injury and infection of the underlying structures.

**Treatment and Aftercare**

Treatment of canker is very difficult and time-consuming, and it does not always result in a cure. All damaged cells must be removed to allow the growth of healthy horn tissue. Treatment must be as hygienic as possible and involves a number of steps.31, 32

**Surgery**

The first step is surgical débridement. All necrotic and abnormal horn is removed with the horse standing or, in severe cases, with the horse under general anesthesia. A tourniquet is applied to the limb in the middle metacarpal or metatarsal region. All abnormal horn is removed so that the area can be thoroughly cleaned and cut with a scalpel blade (Fig. 93-28).

The transition between abnormal and healthy horn is determined during paring with a hoof knife. A cut is made around the frog to define the surgical field. Then, beginning from the palmar or plantar surface, the entire frog is removed (Fig. 93-29). It is important not to cut too deeply...
in near the apex of the frog. Alternatively, cryotherapy can be used. Normal epithelium is then able to grow from the remaining healthy tissue.

In most cases, removing the abnormal horn while sparing the stratum germinativum is adequate. A new frog grows within a few months (Fig. 93-30). The foot is bandaged during this time, so this treatment is labor intensive and time consuming for the owner.

LOCAL TREATMENT

The second step involves local treatment, which consists of disinfection, drying, and hardening of the horn. The hoof is cleaned and disinfected with povidone-iodine scrub and treated with povidone-iodine-soaked bandages for 2 to 3 days. Daily bandage changes are required thereafter.

When healing is observed, a shoe with a pad is applied. The pad must be removable so that the area can be cleaned with povidone-iodine scrub and rinsed with povidone-iodine solution daily. The defect is covered daily with a mixture of 20 g iodoform iodine, 20 g zinc oxide, 20 g tannic acid, and 40 g metronidazole; this mixture acts as a disinfectant, astringent, and drying agent. The wound is then bandaged or covered with gauze and protected with the pad.

Administration of local or systemic antibiotics might be necessary; chloramphenicol and metronidazole are particularly effective. Systemic antibiotics should be administered when more than one hoof is affected. The horse should be given biotin and zinc supplements.

The horn defect becomes smaller as it heals (see Fig. 93-30). The persistence of soft greasy horn usually indicates recurrence of the disease. Repeated surgical débridement is required in some cases. Treatment entails many months and requires good owner compliance. Sanitary stall conditions also are important.

Figure 93-30. Progressive healing is shown 4 months after removal of the entire frog.

DISORDERS OF THE COLLATERAL CARTILAGES

Mineralization

Etiology

Mineralization of the collateral cartilages of the distal phalanx (side bone) is a common radiographic finding in the front feet of heavy horses. Ossification of the collateral cartilages has been considered as a part of the normal aging process, and factors such as heavy bodyweight, working on hard surfaces, repetitive concussion, poor conformation, improper shoeing or trimming, and other foot problems are often mentioned as possible causes.

However, large side bones have also been found in young horses that have not yet started working; therefore an inherited tendency to develop side bones has been suspected. Side bones are more common in mares than in stallions and geldings. Extensive ossification is more commonly found in the lateral than the medial cartilage.

Diagnosis

Ossification of the collateral cartilages is most often an incidental finding. Lameness associated with side bone is difficult to confirm. It is important to correlate radiographic findings with signs of pain. Radiographs reveal ectopic ossification emanating from the proximal aspects of the palmar or plantar eminences of the distal phalanx in the area of the collateral cartilages (Fig. 93-31). Because separate centers of ossification exist in these cartilages, these findings should not be confused with fractured side bones (Fig. 93-32), although in rare cases the side bone can fracture (Fig. 93-33).

Digital manipulation of the collateral cartilages can reveal loss of pliability and pain. Lameness is most marked when the horse is turned at a trot on a hard surface. A palmar digital nerve block on the suspected side of the hoof should improve the painful gait. Increased radiopharmaceutical uptake (scintigraphy) associated with a different radiographic appearance from that of other ossifications of the front feet was a conclusive sign of clinical significance in a recent report of 21 Finnish horses. Ossification of the cartilages is commonly associated with obscure lameness problems, but most often ossification is not the cause.

Treatment

Once ossification of the collateral cartilage has started, it cannot be stopped, and specific treatment is not available. However, if the side bones are suspected as the cause of lameness, rest and administration of NSAIDs would be the logical initial treatment. Any foot imbalances should be corrected, and breakover should be moved caudally on the foot by rolling of the toe. The heels should have as much opportunity for expansion as possible, which is especially important for unbalanced or sheared heels.

A fracture of an ossified cartilage is treated conservatively with NSAIDs and an extended period of stall rest or small paddock turnout (8 to 12 weeks) followed by controlled exercise on level surfaces for 6 to 8 months. It is most likely that after this period of time, the fracture line will still be visible on radiographs but surrounded by proliferative...
exostosis (see Fig. 93-33). In refractory cases, unilateral palmar digital neurectomy can be performed. Small fragments can be removed eventually if any signs of sequestrum formation are observed. An incision 1 to 2 cm parallel to the palmar or plantar coronary band gives access to the proximal part of the collateral cartilage. No attempts should be made to remove large proximal fragments.39

Necrosis

Necrosis of the collateral cartilage (quittor) is characterized by an intermittent purulent discharge and sinus tract formation at or proximal to the coronary band in proximity to the collateral cartilage. These lesions are chronic and do not heal. Lameness occurs in the acute stages but might show remission when the lesion appears to be healing. Usually a mixed bacterial infection is present, associated with subsequent necrosis of the cartilage, as the result of injury to the cartilage itself or to the adjacent soft tissue.40 The quittor condition can develop secondary to a penetrating wound through the sole where infection has gained access to the collateral cartilage.

Diagnosis

Clinical signs of quittor include enlargement over the affected collateral cartilage with one or more chronic sinus tracts that continue to drain. The most important differential diagnosis is a chronic ascending infection of the white line that breaks and drains at or slightly proximal to the
coronary band. With quittor, the swelling is usually more diffuse and is located more proximally over the collateral cartilage.

Radiography can be helpful to detect foreign bodies or to rule out involvement of the middle or distal phalanx. The depth and direction of the draining tracts are determined radiographically after injection of a contrast medium or insertion of a flexible metal probe into the tract.41

Treatment
Prior to surgery the region is clipped and the hoof is trimmed and rasped, scrubbed, and placed in a povidone-iodine–soaked bandage for 24 hours. Once the horse is anesthetized, a tourniquet is applied. The foot is held in maximal extension during dissection to tighten the joint capsule and retract it from the area of dissection, minimizing the risk of accidental penetration into the distal interphalangeal joint.40 A slightly curved incision beginning just dorsal to the coronary band over the diseased collateral cartilage is made (Fig. 93-34). The flap is dissected distad to expose the collateral cartilage, and a probe is used to identify the draining tract. Alternatively, diluted methylene blue can be injected into the tract to identify it during dissection.

Necrotic cartilage is recognized by its dark blue or reddish blue appearance. All of the necrotic tissue and cartilage is removed until healthy margins remain. Subsequently, arthrocentesis of the distal interphalangeal joint is performed and the joint is distended with polyionic fluid to assess the integrity of the joint capsule axial to the removed portions of the collateral cartilages. In case of accidental laceration of the joint capsule, the joint must be flushed with large amounts of fluid through a needle placed in the dorsal aspect of the joint capsule.

After débridement, the defect is closed with 2-0 monofilament absorbable suture material in a simple interrupted pattern. An injection of 2 mL gentamicin into the joint protects it from developing an infection. If necrotic cartilage extends distal to or below the coronary band, a hole is drilled in the hoof wall over the ventral-most limits of the excised cartilage to provide drainage (see Fig. 93-34). After extensive flushing, the proximal skin incision is closed with nonabsorbable tension sutures, and the wound is packed through the hole in the hoof wall using antiseptic-soaked gauze sponges. The surgical site is protected with a sterile bandage.

The following day the bandage is removed and the wound is flushed. Bandages are changed every other day until all evidence of infection has subsided and a healthy bed of granulation tissue is present. When this occurs, a short limb cast can be applied to the limb for 8 to 10 days to minimize movement at the suture line and to encourage primary healing. After removal of the sutures, bandaging is continued until granulation tissue fills the defect and epithelium begins to cornify.

Fractures of the distal phalanx are diagnosed in horses of all ages, even very young foals.42,43
Etiology and Classification

Fractures of the distal phalanx are caused by acute trauma such as a kick toward a hard, nonmovable object. Most often fast or excessive work induces fractures of the distal phalanx. Laceration of the hoof capsule results in fractures as well. The forelimb is more commonly involved than the hindlimb.

Fractures of the distal phalanx are classified into the following types (Fig. 93-35):

I. Abaxial fractures without joint involvement
II. Abaxial fractures with joint involvement
III. Axial fractures with joint involvement
IV. Fractures of the extensor process
V. Multifragment fractures with joint involvement
VI. Solar margin fractures

Some complicated fractures cannot be assigned to one of these classifications.

Clinical Symptoms and Diagnosis

The patient usually shows an acute, moderate to severe lameness accentuated during turns. The hoof and distal phalangeal region are warm to the touch, and an increased pulse can be palpated over the palmar or plantar arteries. Pressure exerted with the hoof testers might elicit a positive response. Arthrocentesis of the distal interphalangeal joint results in a blood-tinged synovial sample when there is articular involvement. Signs are relieved by regional anesthesia of the distal phalangeal region. In the differential diagnosis, a hoof abscess should be considered.

Radiography confirms the diagnosis in most cases. However, occasionally it is difficult to detect a fracture line because of minimal displacement. Additionally, the irregular border of the distal phalanx and debris on the hoof capsule can make recognition of the fracture difficult. It is important to take several radiographs from different angles. Abaxial nonarticular fractures are usually difficult to recognize because they are normally only minimally displaced.

Treatment

Fractures of the distal fragment can be managed with fragment removal, cast application, compression screw fixation, and neurectomy. Foals are best treated with stall rest.

Abaxial Fractures (Types I and II)

These fractures are supported for 2 months by application of a fiberglass cast around the hoof capsule. Subsequently, a bar shoe with large side clips is applied to the hoof, providing support to the heels to limit hoof expansion during loading. NSAIDs are administered to reduce the pain level and allow the horse to bear weight on the foot. Stall rest for 2 to 4 months is required. Follow-up radiographs are taken to evaluate fracture healing.

A reasonable prognosis can be given for future use. It usually takes 4 to 6 months for the fracture to heal. However, radiographically the fracture line is visible much longer. Initially a fibrous union develops, which ossifies at 6 to 12 months. In some cases, a nonunion develops.

Axial Fractures (Type III)

Axial fractures may be managed conservatively or surgically.

NONSURGICAL MANAGEMENT

The same type of treatment is used as that for abaxial fractures (see earlier). However, it is important to prolong the rest period: 4 months of stall rest followed by 4 months of hand-walking exercise. Additionally, the horses should be
shod for 6 to 8 months with a bar shoe. A guarded prognosis is given for horses older than 3 years that are to be used as future riding animals, whereas horses younger than 2 years have a good prognosis.

SURGICAL MANAGEMENT
On the day prior to surgery, the entire hoof is thoroughly cleaned and the sole trimmed and all crevices removed. The entire hoof wall surface is rasped and the foot placed overnight in a bandage soaked with an antiseptic (Betadine).

For surgery, the animal is anesthetized and positioned in lateral recumbency on the surgery table. The use of a fluoroscope during the surgery aids in achieving correct positioning of the screw. The entry point through the hoof capsule is determined by taping a radiodense object to the lateral hoof wall and taking a lateromedial radiograph. By comparing the radiographic image with the objects on the hoof wall, the entry point is determined and marked on the hoof wall with an awl. The final preparation of the hoof and phalangeal region for aseptic surgery is completed.

Using a 10-mm diameter drill bit, a hole is made through the hoof capsule parallel to the sole surface and aligned with the bulb of the heel. The hole is continued until the drill bit reaches the distal phalanx. A pilot hole is drilled into the third phalanx with a small drill bit until it crosses the fracture. This depth cannot usually be determined without the help of fluoroscopy or intraoperative radiographs. Once the desired location and direction of the drill bit is determined, the glide hole is prepared (Fig. 93-37). Frequent fluoroscopic views will help identify the moment when the fracture plane is crossed with the drill bit. At this point, the drill bit is removed and exchanged with the one used for drilling the thread hole, which is performed through an insert drill sleeve. Care is taken to identify the exit point through the opposite fragment to prevent inadvertent trauma to the sensitive lamina. After countersinking and tapping, a 5.5-mm cortex screw of predetermined length is inserted and solidly tightened.

Tangential radiographs are taken directed at the exit point of the screw tip to ensure correct length. Screws that are too long are exchanged for shorter ones. Conventionally, one screw is inserted without taking too big a risk of entering vital structures. With the help of computer-assisted navigation (see Chapter 14), two screws can safely be implanted. The hole in the hoof capsule may be filled with an antibiotic-soaked sponge and placed under an aseptic pressure bandage or closed with antibiotic-impregnated polymethylmethacrylate (PMMA). Once the horn defect is dry (if it is not immediately filled with PMMA) it is filled with artificial horn.

Postoperatively the horse is kept in a box stall for 4 months followed by hand-walking exercise of an additional 4 months. Barring any complications, the screw may be left in place; otherwise it is removed when problems develop. The prognosis for a pleasure horse is guarded. Complications include postoperative infection and abscess formation.

Extensor Process Fragments (Type IV)
ETIOLOGY
These fragments have three known etiologies: hyperextension injury, avulsion by the extensor tendon, and a separate center of ossification (osteochondrosis, which may be bilateral).

CLINICAL SYMPTOMS AND DIAGNOSIS
Some horses show no clinical signs, and the presence of a fragment of the extensor process is found incidentally. Often the clinical signs are similar to those exhibited with other articular disorders of the distal interphalangeal joint. A routine lameness examination including perineural and

Figure 93-37. A, Dorsopalmar fixation of a type III fracture with one cortex screw inserted in lag fashion. B, Lateromedial fixation of a type III fracture with two cortex screws inserted in lag fashion.
intra-articular anesthesia and a radiographic examination permit a definitive diagnosis (Fig. 93-38, A).

**TREATMENT**

**Small fragments**

Small fragments (see Fig. 93-38, A) should always be removed because they are mobile and have contact with the articular surfaces. Fragment removal is accomplished by routine arthroscopy (see Fig. 93-38, B). Adjunctive therapy with intra-articular hyaluronan is encouraged. Postoperatively, the phalangeal region is kept under a bandage for 3 weeks and the horse rested for 6 to 8 weeks.

**Large fragments**

There is no ideal treatment for large fragments (Fig. 93-39). Therefore, conservative therapy is usually tried first. Insertion of one or two screws in lag fashion has been described, but only rarely is a rigid fixation achieved. Therefore, if lameness persists after conservative management, surgical treatment is recommended. The fragment is divided into smaller pieces and these smaller pieces are removed under arthroscopic supervision. Generally, a good prognosis can be given. Postoperatively a fiberglass cast or a compression bandage should be applied over the surgery site.

**Multifragment Fractures (Type V)**

Multifragment fractures are always associated with severe lameness. Radiographically, several fracture lines can be appreciated (Fig. 93-40). Application of a fiberglass cast may be tried; however, these fractures have a poor prognosis for future soundness. Therefore, euthanasia may be considered.
Alternatively, a neurectomy can be performed if euthanasia is not an option for the owner.

**Solar Margin Fractures (Type VI)**

Solar margin fractures do occur often and are underdiagnosed. Direct or blunt trauma, possibly caused when the horse kicks a hard, immobile object, are common causes of solar margin fractures. These fractures can also develop as a result of chronic laminitis. Most solar margin fractures heal by bone union; rarely, resorption of small fragments can occur. Surgical removal of fragments has been reported in individual cases.

**Arthroscopy**

Arthroscopy of the distal interphalangeal (DIP) joint (Fig. 93-41) has replaced arthrotomy, as it did in other joints. The advantages include the small approach portals, the small risk of postoperative infection, and the shortened convalescent period. Indications for arthroscopic interventions include fragment removal from the extensor process, lavage in cases of infection, and curettage of subchondral cystic lesions.

**PREPARATION**

The hoof should be thoroughly cleaned the day before surgery, and the coronary band and the phalangeal region should be clipped. The entire area is scrubbed and placed overnight in an antiseptic bandage. The shoe may be left in place.

For arthroscopic interventions in the forelimb, the animal is positioned in dorsal recumbency on the surgery table. Lateral recumbency is usually selected in the hind limb because the reciprocal apparatus makes manipulation easier in this position. An Esmarch bandage is applied to prevent intraoperative bleeding. Because of the location of the surgery site, meticulous attention is paid to the draping procedure. The use of a sterile incise drape (Ioban, Johnson & Johnson, Raritan, NJ) is advisable.

**Surgical Technique**

**Dorsal approach**

With the DIP joint in an extended position, a needle is advanced in a dorsolateral to distomedial direction from 2 cm proximal to the coronary band. Withdrawal of synovial fluid ensures the correct placement of the needle. The joint is distended with gas or with 20 mL Ringer’s lactate solution.

The arthroscope portal is prepared with a no. 11 scalpel blade introduced into the joint along the needle, and the needle is withdrawn. Immediately after the incision is prepared, the sleeve and the blunt obturator are carefully advanced together into the joint with a rotating movement. The obturator is replaced by the arthroscope.

Working with a dorsolateral arthroscope portal allows inspection of a medial fragment and its removal through an instrument portal positioned directly over the fragment (see Fig. 93-41). The joint is very small, providing little room for recognition of the anatomic landmarks. The middle phalanx is recognized by its articular cartilage surface and the proximal prominent ridge, which provides access to the dorsal outpouching of the joint. The synovial membrane, located at the dorsal aspect of the joint cavity, is covered with synovial villi, which partially obstructs the view. Often the osteochondral fragment of the extensor process is hidden behind the villi. The surface of the fragment is usually rough and irregular.

The first key to identifying the fragment is to recognize the separation between the fragment and the parent portion of the bone. The abaxial aspect of the joint should be inspected initially to provide an overview of the condition of the joint. It is possible that displaced small fragments can be found in these locations.

Most fragments are well attached. Insertion of an elevator between the fragment and the distal phalanx and careful manipulation loosens most fragments. It is important to remove a significant portion of the attachments of the extensor tendon and surrounding tissues from the fragment before attempting to remove the fragment with rongeurs. Once purchase is achieved on the fragment, rotating movements are performed to dislodge the remaining attachments.

---

**Figure 93-41.** Typical positions of the arthroscope and instruments during arthroscopy of the distal interphalangeal joint.
Because of the softness of the fragment, it is usually removed in pieces. The fracture bed is inspected and curetted. Introduction of the arthroscope through the instrument portal allows inspection of the fragment bed from a different view and occasionally the detection of other small fragments. The joint is then flushed and the portals closed with two simple interrupted sutures of an absorbable monofilament material.

A postoperative pressure bandage is maintained for 2 weeks. The portals for the surgery heal slower than such portals in other joint regions. Therefore, there is an increased risk of infection. Additionally, intra-articular injections such as hyaluronan are delayed for about a week. The horse is kept in a box stall for 4 weeks and can then slowly return to work.

The prognosis depends on the nature of the problem, the age of the patient, and the arthroscopic findings during surgery. In young horses, a good prognosis usually can be given, whereas in older horses with concomitant osteoarthritis, the prognosis for successful return to work decreases.

**Palmar approach**

An arthroscopic approach to the palmar aspect of the distal interphalangeal joint has been described. The horse is positioned in lateral recumbency and the joint is distended through a dorsally placed needle. Observation of the process of joint distention allows identification of the best palmar location to access the joint. A needle is placed into the site to facilitate correct scope positioning.

**Arthrotomy**

Prior to the introduction of arthroscopy, fragments were removed through arthrotomy approaches. Arthrotomy allows exploration of only a small part of the joint without a large skin incision. Therefore, this type of intervention is justified only under certain circumstances, such as for removing excessively large fragments.

The skin incision is made on the midline, starting 4 cm proximal to the coronary band and ending at the coronary band. The common digital extensor tendon is split, and a Gelpi retractor is inserted to allow inspection of the most proximal tip of the fragment. The fragment is grasped with Allis tissue forceps and an incision is made around it with a scalpel. The incision is closed using routine technique.

Occasionally, a trephine hole is made distal to the coronary band over the midline down to the distal phalanx. This can allow removal of a large fragment without causing extensive damage at the dorsal aspect of the joint and the coronary band. The defect in the hoof wall is managed as described earlier.

**Fractures of the Distal Sesamoid Bone**

Fractures of the distal sesamoid bone (DSB) occur rarely. They are diagnosed more often in the forelimbs. Four different types are distinguished: avulsion fractures, simple fractures of the body, comminuted fractures, and frontal fractures.

Avulsion fractures of the distal margin are often found in conjunction with navicular disease. Therefore, these fractures are considered part of an osteoarthritic syndrome (see later in this chapter).

Most of the simple fractures occur abaxially in a vertical or slightly oblique direction (Fig. 93-42). Some displacement is possible. Multifragment fractures are rare and in most cases carry a poor prognosis. Fractures in the frontal plane are highly unusual (Fig. 93-43).

**Etiology**

Most fractures of the DSB have a traumatic origin and are the result of excessive or repetitive loading through the middle and distal phalanx and the DDF tendon. Occasionally, a pre-existing pathologic condition in the DSB predisposes it...
to fracture (Fig. 93-44). In these cases, chronic navicular disease is usually implicated.

**Clinical Signs and Diagnosis**

Clinical signs include an acute moderate to severe weight-bearing lameness associated with an intense pain reaction to turning, increased pulsation of the palmar or plantar arteries, and positive reaction to the application of hoof testers. The low palmar or plantar nerve block is usually diagnostic. All standard radiographic views of the DSB should be taken (lateromedial, tangential, and oblique) to rule out the potential presence of a bipartite DSB (two ossification centers) or other disorders. Air shadows of the sulci of the frog will project over the DSB and can be mistaken for fracture lines. Therefore, it is important to fill them with modeling compound (such as Play-Doh) before taking the radiographs.

**Treatment**

Management options for fractures of the DSB include conservative and surgical techniques. Callus formation is rare, and often syndesmoses are formed (fibrous tissue union).  

**Nonsurgical Management**

Corrective shoes are recommended to protect the DSB. Therefore, nonsurgical management involves stall rest and an elevated bar shoe (Fig. 93-45) for 4 months, followed by small paddock exercise and a shoe with thickened branches.  

One option involves fixation of the distal limb in an extremely flexed position using a fiberglass cast, which relieves excessive stresses on the DSB. Acceptance of the cast takes a special patient, and healing requires about 6 months. Despite these measures, the prognosis for a future pleasure horse is guarded.

**Surgical Management**

The surgical options include screw fixation and neurectomy. Insertion of a cortex screw in lag fashion provides stability and promotes bone union. The difficulty is in correct placement of the screw, avoiding penetration of the DIP joint and the palmar tendon sheath (Fig. 93-46). Close monitoring through fluoroscopy or multiple radiographic images is of utmost importance. The application of specially developed radiolucent aiming devices (Fig. 93-47) is mandatory for a correct screw placement. Computer-assisted navigation is an alternative technique (see Chapter 14).

Effective preoperative preparation of the hoof is initiated the day before surgery, as described earlier. The entry point through the hoof wall is determined and marked with the help of fluoroscopy. The horse is placed under general anesthesia and positioned in lateral recumbency on the surgery table. The surgical site is prepared for aseptic surgery.

The aiming device is applied to the hoof and adjusted with the help of fluoroscopy. The 3.5-mm glide hole is made, just crossing the fracture plane. The insert drill guide is inserted into the glide hole, and a 2.5-mm thread hole is drilled into the opposite fragment. After tapping, a 3.5-mm cortex screw of estimated length is inserted and tightened. With the help of a dorsopalmar radiograph, correct positioning and length are verified.

Healing of the fracture takes 6 to 8 months, during which stall rest and hand-walking exercise are implemented. Barring any complications, the screw is left in place.

The prognosis for athletic competition is guarded, but for pleasure riding it is favorable. Application of computer-assisted navigation greatly improves precision in screw placement and speeds up the surgery. To allow the horse to return to competitive work, it is often necessary to perform a neurectomy.
PALMAR OR PLANTAR DIGITAL NEURECTOMY

General Considerations

Neurectomy is one of the oldest surgical procedures described in horses.\(^6^6\) Palmar or plantar digital neurectomy is a viable option for alleviating pain in horses with certain kinds of chronic lameness, particularly navicular disease. A thorough clinical examination and proper case selection are critical. For example, digital neurectomy is contraindicated in horses with laminitis or infection of the distal interphalangeal joint.

Various techniques for digital neurectomy have been described. The operation may be performed with the horse standing\(^6^7\) or in lateral or dorsal recumbency under general anesthesia.\(^6^8\) There are various methods of denervation. With the horse standing, the procedure is carried out quickly and none of the risks of general anesthesia are encountered. With the horse in dorsal recumbency, repositioning the horse to access both sides of the limb is not required,\(^6^8\) and a tourniquet is not necessary because minimal bleeding occurs. A nonsteroidal anti-inflammatory drug should be administered postoperatively and the horse kept in a box stall for 4 weeks. The horse is then slowly reconditioned by walking during another 4 weeks.

Re-innervation can occur when the severed nerve endings re-establish contact with each other. This can happen as early as 6 months postoperatively, depending on the technique used. However, ideally this does not happen for many years.\(^5^5,6^9\) Neuritis and neuroma formation are common complications, particularly in the proximal nerve stump; depending on the study, up to 20% of patients are affected. These lesions are very painful, and in selected cases they must be treated with local injections of triamcinolone acetate (5 to 10 mg for each neuroma), sarrapin, or alcohol blocks. Rupture of the DDF tendon can occur after neurectomy, especially if it was compromised before surgery. Another sequel is laminitis, which can develop after a second operation or with injury of the blood vessels.

Special techniques are used in an attempt to prevent or at least delay regrowth of the severed nerve ends as well as to reduce the risk of neuroma formation. Various methods have been described for cutting the nerve and treating the severed nerve ends. The guillotine technique is the most commonly used.\(^5^5,6^9\) This technique can be applied through one large or two small incisions, as described later.

Electrocoagulation is a less commonly used method. Other methods include epineural capping, inserting the nerve in a hole drilled into the proximal phalanx\(^5^5,7^1\) or ligating the nerve. A valid alternative to digital neurectomy is cryoneurectomy, in which the nerve is frozen to as low as...
Other alternatives include topical application of chemicals and injection of neurotoxins such as cobra venom. Carbon dioxide laser treatment of the proximal nerve stump has reduced the development of neuromas.

In certain countries, animal welfare legislation and equine sports associations (for instance, the International Equestrian Federation [FEI]) prohibit horses that have had a digital neurectomy from competing in official events. As a consequence, various methods of detecting a neurectomy have been developed.

**Palmar Digital Neurectomy in the Pastern Region Using One Skin Incision**

The horse is positioned in dorsal recumbency, and the limbs are extended and tied to restraints attached to the ceiling. The surgical field is clipped, prepared for aseptic surgery, and draped. The nerve is palpated, and an approximately 6- to 8-cm incision is made in the pastern skin directly over the nerve (Fig. 93-48, A and B). Usually the skin incision is made along the dorsal edge of the DDF tendon, which directly exposes the nerve.

The ligament of the ergot is identified and split longitudinally (see Fig. 93-48, C and D), allowing access to the neurovascular bundle located beneath it. Splitting the ligament provides an extra layer to be closed over the severed nerve and potentially reduces postoperative irritation and subsequent neuroma formation. Additionally, mistakenly transecting the ligament instead of the nerve can be prevented with this technique. The nerve is isolated within the neurovascular bundle and well separated from the artery (see Fig. 93-48, E and F). The neurotomy is initially performed proximally and then distally, followed by removal of the loose piece of nerve (see Fig. 93-48, G).

The ligament of the ergot is closed in a continuous pattern, and the skin is closed with simple interrupted sutures. Aftercare is the same as that for the method using a small incision, described under “General Considerations.”

---

**Figure 93-48.** Illustration of the neurectomy procedure for the phalangeal region through one incision. A, Location of the skin incision. B, The skin incision has been made. C, The ligament of the ergot is split longitudinally and separated (D), giving access to the underlying tissues and the neurovascular bundle. E, The structures of the neurovascular bundle are separated, and F, the nerve is isolated. G, A 2-cm piece of nerve is excised.
Palmar Digital Neurectomy in the Pastern Region
Using Two Small Incisions

The location of the nerve is palpated and two approximately 1.5-cm skin incisions are made directly over the nerve (Fig. 93-49, A and B). The distal skin incision is located at the distal end of the pastern region at the transition to the bulb of the heel. The proximal skin incision is selected at the proximal end of the pastern region at the transition to the metacarpophalangeal joint.

The tissue is bluntly dissected longitudinally with a mosquito forceps so that the dorsal and palmar aspects of the nerve are freed (see Fig. 93-49, C). It is important that the nerve and artery be well separated. Proximally the nerve might be obscured by the ligament of the ergot, which runs superficial to the nerve at a slightly different angle. The nerve is always covered by fascia, and it can be surprising how deep a dissection is required for its isolation.

Once the nerve has been freed proximally and distally, it is alternately pulled at either end to ensure that the correct structure has been exposed. The nerve is pulled up with a mosquito forceps, held with tissue forceps, and cut sharply as far distally and proximally as possible with a no. 15 scalpel blade (see Fig. 93-49, D and E). One clamp is applied to the proximal end and another one to the distal end of the severed nerve segment, and tension is applied to ensure that all attachments are eliminated and the nerve segment can be completely removed (see Fig. 93-49, F and G). The skin incisions are closed with 2-0 nonabsorbable suture material.

The advantages of this technique are the small size of the skin incisions, short time of surgery, and low incidence of neuroma formation.

Repeate Palmar Digital Neurectomy

A second neurectomy might be necessary when re-innervation occurs and the horse becomes lame again. For this procedure, a long incision is usually made so that the nerve can be adequately freed. This procedure is often more difficult than the initial operation because the nerve is generally very closely associated with the artery.

Small neuromas are always seen in the proximal aspect of the previous surgical field. These nodules can be easily palpated in horses that have had a neurectomy. Sometimes the regrown nerve is surrounded by a large amount of scar tissue, which makes the operation more difficult. Only the neuroma and part of the distal nerve should be removed. Skin closure and aftercare are the same as for the other neurectomy procedures.

High Lateral and Medial Palmar Neurectomy

The goal of high lateral and medial palmar neurectomy is to disrupt afferent and efferent nerve tracts proximal to the division into palmar and dorsal branches to prevent pain sensation from chronic disease processes innervated by the dorsal branches of the lateral and medial palmar nerve. This is usually performed proximal to the flexor tendon sheath, because locating and removing the nerve is easy in this location (Fig. 93-50). Also, there is little relative movement in this area, so that the nerve endings are less traumatized. The operation is carried out with the horse in dorsal recumbency. The skin is incised immediately proximal to the flexor tendon sheath on the lateral and medial aspects of the metacarpus. The nerve is located, isolated, and removed. Aftercare is the same as for the other techniques.

SURGICAL MANAGEMENT OF NAVICULAR SYNDROME

Navicular disease is a degenerative disorder that involves the DSB and its surrounding structures. The etiopathogenesis of the condition is multifactorial, and many theories have been
proposed; these theories are discussed in detail in the literature. Vascular and mechanical theories continue to be debated as the primary cause of the disease.

**Treatment**

There is no cure per se for navicular disease. Its management concentrates on abolishing the symptoms and clinical signs.

**Nonsurgical Management**

Management strategies include corrective shoeing, nonsteroidal anti-inflammatory drugs (NSAIDs), and vasodilators such as isoxsuprine or metrenperone. Intra-articular administration of hyaluronan with or without corticosteroids into the distal interphalangeal joint or in the navicular bursa can provide transient relief of clinical signs. The biphosphonate tiludronate (Sanofi-Aventis, Paris) has demonstrated positive effects in the treatment of recent cases (less than 6 months of lameness) of navicular disease.

Another novel medical treatment is based on the pathophysiologic mechanism that podotrochlosis is associated with an increase of the intraosseous pressure in the navicular bone. The increase of pressure might be caused by an accumulation of osmotically active substances in the interstitium, as has been described in case of compartment syndrome. Therapy with coumarin is proposed. This drug is successfully used in humans to reduce high-protein edemas.

**Surgical Management**

Surgery is usually reserved for cases of navicular syndrome that have not responded to conservative treatments such as corrective shoeing and medical management. Three surgical procedures are currently available: navicular suspensory desmotomy, palmar digital neurectomy, and periarterial sympathectomy. These surgical procedures should be combined with balancing the feet and applying corrective shoes.

**DESMOTOMY OF THE SUSPENSORIG LIGAMENTS**

Desmotomy of the suspensory ligaments (DSL) of the DSB has been proposed on the assumption that the syndrome has a mechanical basis. The proposed mechanism of action of the surgery reduces the forces on the navicular bone and perinavicular structures associated with the caudal weight-bearing phase of the stride (the portion of the stride where the suspensory ligaments are loaded).

The DSB has its own supporting ligaments: proximally, the collateral sesamoidean ligaments (CSLs) and distally the impar ligament (IL) and the chondrosesamoidean ligaments (Fig. 93-51). The suspensory ligaments of the DSB are broad, elastic structures containing an abundance of nerve fibers. They originate at the dorsal aspect of the proximal phalanx and insert primarily on the proximal border of the DSB (Fig. 93-52, A). A branch of each ligament, the chondrosesamoidean ligament, also inserts on the axial surface of the adjacent collateral cartilage and the palmar process of the distal phalanx.

The biomechanics of the DSB and its suspensory apparatus are not completely understood and are explained mainly with the help of theoretical models. It is generally accepted that the CSLs anchor the DSB and prevent its descent during weight bearing. However, the exact biomechanical implications of the CSL during loading are difficult to explain because the ligament passes over two joints, and time and maximum amount of tension depend on the foot or pastern axis and hoof conformation, as well as on the phase of the stride. Nevertheless, it is argued that
exercise should be initiated soon after surgery and is continued for 3 weeks. Thereafter, a gradually increasing exercise program is implemented with the goal of achieving full work levels by 3 months after surgery. Postoperative complications are rare but include wound dehiscence, infection, local swelling, and postoperative scarring.

Preliminary results from the United Kingdom were encouraging: 13 of 16 horses treated with CSL desmotomy were able to work without lameness. In the same year, another author reported clinical improvement in 50% of 57 horses. Two additional studies reported success rates of 15 of 21 horses and 12 of 17 horses, respectively, with the latter horses being sound at least 6 months after surgery. In a review of 118 horses suffering from navicular syndrome that were treated with navicular suspensory desmotomy, 76% were sound at 6 months, and 43% were sound after 36 months.

All of the following conditions were associated with a diminished response: the presence of flexor cortex defects, the presence of proximal border enthesiophytes, mineralization of the DDF tendon, and medullary sclerosis of the DSB. Horses with more than 1 year’s duration of clinical signs had a poor prognosis. The procedure is not recommended in horses with inflammatory disease of the distal interphalangeal joint and the navicular bursa, but horses with new bone growth at the site of insertion of the suspensory ligaments (enthesiophytes) are considered excellent candidates for this surgery. The procedure should be attempted early in the course of the syndrome.

It was originally stated that desmotomy of the CSL should modify the biomechanical forces acting on the DSB, but clinical improvement could also be the result of transection of the sensory fibers that course within the suspensory ligaments. It seems that the procedure is more effective in improving clinical signs on a short-term basis (6 to 12 months), and the lameness can recur later on because of reinnervation of the sensory fibers in the CSL.

PALMAR DIGITAL NEURECTOMY
The most commonly performed surgical technique to abolish lameness associated with the navicular syndrome is palmar digital neurectomy (see earlier).

PERIVASCULAR SYMPATHECTOMY AND FASCIOLYSIS
Perivascular sympathectomy and fasciolysis around the lateral and medial digital artery and vein have been described for the treatment of navicular syndrome. A 10-cm skin incision is centered over the lateral and medial proximal sesamoid bones. The subcutaneous tissues and fascia are carefully transected as well and the neurovascular bundle is identified. The artery and vein are isolated from their perivascular tissues and adventitia over the entire length of the surgical site. The nerve is isolated from its surroundings as well. Inadvertent traumatization of the vessels and the nerve should be avoided at all costs. Through this dissection the sympathetic nerve supply of the vessels is stripped, which results in a prolonged vasodilation. The subcutaneous tissues and the skin are closed in routine fashion.

A significant increase in skin temperature caused by increased blood circulation in the region could be demonstrated at 8 and 20 weeks postoperatively with the help of...
thermography in 30 horses.\textsuperscript{93} In each horse, one forelimb was operated on, whereas the other served as a control. A significant increase in hoof horn growth could be seen in the experimental limb compared to the control limb. In a review of 79 horses suffering from navicular syndrome that were treated with perivascular sympathectomy and fasciolysis, 73\% were sound and returned to the intended use. The mean duration of follow-up was 23.6 months (range, 3 to 72 months).\textsuperscript{93}

SURGICAL MANAGEMENT OF LAMINITIS

Laminitis is characterized by a breakdown of the connective tissue suspensory apparatus of the distal phalanx inside the hoof wall. As a result of lamellar pathology, the distal phalanx is no longer supported by the laminar attachment and starts to displace. As soon as the first signs of displacement are recognized, the disease becomes chronic.

There is a direct relationship between the degree and speed of movement of the distal phalanx away from the hoof capsule and the severity of damage to the laminae at the initial insult. Therefore, the most useful diagnostic and monitoring aids in the course of the disease are high-quality radiographs in both lateromedial and dorsopalmar (horizontal) projections.

Clinical Signs

Clinical signs, severity of damage, and response to therapy vary among individual horses, but it is widely accepted that the single most important factor influencing the final outcome of equine laminitis is the severity and extent of the initial damage to the internal anatomy of the foot.

Diagnosis

Clinical signs are very typical, and the radiographic examination further helps to diagnose this condition.

Treatment

Treatment of laminitis consists of dietary management, medical treatment, soft bedding, and hoof care. In all phases of the hoof care, corrective shoeing and trimming should aim to reduce stress to the damaged lamellae by minimizing the distracting forces affecting the displacement of the distal phalanx (rotation or sinking). DDF tenotomy is a salvage procedure for horses with chronic refractory laminitis.

Tenotomy of the Deep Digital Flexor Tendon

The rationale for tenotomy of the DDF tendon is based on the biomechanical forces in the foot. The procedure is performed to reduce the palmarly directed pulling forces of the DDF tendon on the distal phalanx and subsequently decrease the shearing stresses on the lamellae of the dorsal aspect of the hoof capsule. It also serves to reduce the pressure of the apex of the distal phalanx on the corium of the sole. Tenotomy of the DDF tendon permits lowering the heels to allow a more normal alignment (derotation) of the distal phalanx using orthopedic shoeing.\textsuperscript{35}

DDF tenotomy can be performed at the midmetacarpal or the pastern area of the limb. Both procedures are equally effective, but tenotomy at the level of the midmetacarpus is preferred for various reasons. It is easier to perform and can be performed in a standing horse, the digital tendon sheath is not invaded, it bears less risk of postsurgical infection, and it leaves some support to the distal interphalangeal joint through fascial attachments. Pastern region DDF tenotomy must be performed under general anesthesia and should be reserved for cases that require a second tenotomy.

Before both surgeries, horses should be shod with a heel extension to stabilize the foot and help prevent postoperative hyperextension or subluxation of the distal interphalangeal joint.

MIDMETACARPAL APPROACH

The hair is clipped from the limb circumferentially from the level of the metacarpophalangeal joint to the carpus. The horse is sedated, and local anesthesia is achieved through a high palmar ring block.

After aseptic preparation of the limb, a vertical incision through the skin, subcutaneous tissue, and paratenon is made directly over the lateral aspect of the DDF tendon, centered at the junction of the proximal and middle third of the MCIII (Fig. 93-53, A). With the help of curved Kelly forceps, the DDF tendon is separated from the neurovascular bundle (Fig. 93-53B), the accessory ligament, and the superficial digital flexor (SDF) tendon. The DDF tendon is elevated out of the incision (see Fig. 93-53, B). During this part of the procedure, an assistant should lift the limb off the table to relieve the tension on the DDF tendon. Care must be taken to avoid elevating the neurovascular bundle located medially to prevent its inadvertent transection together with the tendon. The elevated tendon is subsequently transected with the scalpel blade. An immediate separation of the ends of 1 to 3 cm is usually noted after complete transection of the tendon.

An alternative tenotomy technique involves the blind transection of the DDF tendon with the help of a blunt bistoury while the animal is weightbearing.\textsuperscript{96} Concomitant transection of the medially located neurovascular bundle can occur with this technique.

The subcutaneous tissue is closed with an absorbable monofilament suture material in a simple continuous pattern. The skin is closed with stainless steel staples.

DISTAL APPROACH

DDF tenotomy is performed with the horse in lateral recumbency under general anesthesia.\textsuperscript{37} A 3-cm vertical skin incision is made along the palmar midline of the pastern region, 1 cm proximal to the bulb of the heel (Fig. 93-54, A). The skin, subcutaneous tissue, and sheath of the DDF tendon are incised, and the DDF tendon is exposed, elevated, and transected (see Fig. 93-54, B and C). The amount of separation of the tendon ends is greater after tenotomy at this level (6 to 10 cm) because there are no attachments to the distal tendon other than the insertion site to the distal
Closure of the tendon sheath, subcutaneous tissue, and skin is routine.

Postoperative Management

Bandages should be maintained for a minimum of 6 weeks to minimize swelling and prevent contamination of the surgery site. The horse is administered phenylbutazone for pain as needed and confined to the stall, wearing a heel extension shoes for 6 to 8 weeks. For midmetacarpal tenotomy, this type of shoe seems to be less necessary. A mild degree of hyperextension of the distal interphalangeal joint occurs, but it is usually self-limiting. Most horses show an initial improvement within 2 to 3 days of surgery. After tenotomy in either location, flexor support for the distal phalanx should develop through attachments of the distal tendon end by 6 to 8 weeks after surgery, and maintenance of a normal hoof–pastern axis without extended heels should be possible. Tension relief after tenotomy appears to last for several months.

Complications directly related to the surgery are rare but can include incision infection and postoperative pain. Chronic pain can result from overloading the SDF tendon before healing, osteoarthritis of the distal interphalangeal joint, or chronic infection of the digit. A flexural deformity of the metacarpophalangeal joint (dorsiflexion) can develop from chronic pain, resulting in an inability to bear weight on the limb and contracture of scar tissue at the tenotomy site.

Prognosis

In a study of 13 horses with chronic laminitis and 12 to 36 degrees of rotation of the distal phalanx from the dorsal hoof wall, the first clinical improvement was noted by the third or fourth day after midpastern tenotomy of the DDF tendon. At the end of 2 weeks after surgery, the horses continued to improve and were willing to walk without the benefit of nerve blocks. Eventually, five horses could be lightly ridden, seven horses were pasture sound, and one horse was euthanized. In another report of DDF tendon transection at the midmetacarpal level in 20 horses with severe acute or chronic laminitis unresponsive to conventional treatment, 11 patients survived less than 1 month after surgery and six horses survived longer than 6 months. Three horses remained lame, and no horse returned to athletic performance.

One study evaluating the effect of DDF tenotomy as a treatment for chronic laminitis in 35 horses (midmetacarpal, 30 horses; midpastern, 5 horses) found that 27 horses (77%) were alive 6 months after surgery and 19 of 32 (59%) horses were alive for at least 2 years. Bodyweight at the time of surgery and the degree of distal phalangeal rotation had no effect on the 2-year survival. Of the horses in this study, 10 became sound enough for light riding, and there was no correlation between the Obel grade of lameness, the degree of rotation, and the ability to be ridden.

Another study evaluating the effect of DDF tenotomy in the midcarpal region of nine horses with severe laminitis associated with complications such as intense pain, rotation more than 15 degrees, perforation of the sole, or evidence of infection of the sole or distal phalanx found an initial survival rate of 100%. Six of the nine horses survived more than 21 months, and the other three were convalescing at the time the report was published. Four of the nine horses could be used for pleasure riding.
Although the recent studies report surprisingly good results, it should not be forgotten that these horses require prolonged and expensive supportive care and often additional surgical interventions. They suffer months of crippling foot pain and recumbency, and everyone involved must be dedicated to the patient.

MUSCULOSKELETAL SYSTEM
CHAPTER 94

Phalanges and the Metacarpophalangeal and Metatarsophalangeal Joints

Alan J. Nixon

MIDDLE PHALANX

The middle phalanx is a relatively compact bone that is loaded predominantly in axial and torsional planes during athletic activity. It articulates with the distal phalanx through a high-motion joint and proximally with the proximal phalanx through a relatively low-motion joint. The middle phalanx is enclosed distally within the confines of the hoof and coronary band, but it is more exposed proximally, particularly over the palmar and plantar eminences.

The middle phalanx is bounded by multiple ligaments and tendons. The common (or long) digital extensor tendons dorsally and the digital flexor tendons palmarly (or plantarly) contribute to motion of the proximal and distal interphalangeal joints and provide resistance to overextension of the distal limb. In addition, the middle phalanx is stabilized by strong lateral and medial collateral ligaments of the proximal interphalangeal joint and the suspensory ligament of the navicular bone.

Fractures of the middle phalanx are most common in Quarter Horses but occur in all breeds. Horses that turn predominantly on their hindlimbs, such as cutting and reining horses, incur comminuted fractures of the middle phalanx almost exclusively in the hindlimbs. More than 70% of middle phalanx fractures in one report involved the hindlimb. Similarly, distraction fractures of the plantar eminences occur primarily in the hindlimbs because of the forces incurred during sudden stops and turns, most likely as an avulsion of the bony insertion of the superficial digital flexor (SDF) tendons.

Fracture Configurations

Middle phalangeal fractures are classified as simple or comminuted and fall into one of four categories: dorsal or palmar or plantar intra-articular osteochondral fractures, palmar or plantar eminence fractures, axial fractures, or comminuted fractures.2

Osteochondral Fractures

Dorsal or palmar or plantar osteochondral fractures are not common.3-6 Most osteochondral fractures occur on the palmar or plantar aspect of the middle phalanx, either lateral or medial to the axial midline (Fig. 94-1). These fractures do not involve the insertion of SDF tendon or distal sesamoidean ligaments and therefore do not distract. Despite the size and intra-articular location of these fragments, development of osteoarthritis is relatively slow. Nevertheless, they have been reported as a cause of lameness, and surgical removal is recommended if a lameness examination confirms the mid-phalangeal region as the site of pain. They can be incidental findings.

Surgical removal of palmar or plantar fragments using arthroscopy is recommended, although open approaches through the digital sheath are described. The arthroscopic portal is made into the voluminous palmar pouch of the proximal interphalangeal (PIP) joint (Fig. 94-2). Access for instruments is provided by a second portal 2 cm distal to the arthroscope, and often an additional portal on the contralateral side of the palmar region of the pastern, especially when removing large palmar fragments. Fragment dissection and removal can be difficult.

Dorsal fragments also can be removed arthroscopically with an approach over the dorsal joint pouch. Limited maneuverability results from the attachment of the extensor tendon immediately distal to the joint. Arthroscopic entry is usually abaxial to the extensor tendon. The prognosis after surgical removal of dorsal and palmar fragments is favorable, unless the fragmentation is associated with early joint degeneration.

Palmar or Plantar Eminence Fractures

Fractures of the palmar or plantar eminence of the middle phalanx can be uniaxial or biaxial. The treatment and

The middle phalanx is a relatively compact bone that is loaded predominantly in axial and torsional planes during athletic activity. It articulates with the distal phalanx through a high-motion joint and proximally with the proximal phalanx through a relatively low-motion joint. The middle phalanx is enclosed distally within the confines of the hoof and coronary band, but it is more exposed proximally, particularly over the palmar and plantar eminences.

The middle phalanx is bounded by multiple ligaments and tendons. The common (or long) digital extensor tendons dorsally and the digital flexor tendons palmarly (or plantarly) contribute to motion of the proximal and distal interphalangeal joints and provide resistance to overextension of the distal limb. In addition, the middle phalanx is stabilized by strong lateral and medial collateral ligaments of the proximal interphalangeal joint and the suspensory ligament of the navicular bone.

Fractures of the middle phalanx are classified as simple or comminuted and fall into one of four categories: dorsal or palmar or plantar intra-articular osteochondral fractures, palmar or plantar eminence fractures, axial fractures, or comminuted fractures.

Osteochondral Fractures
Dorsal or palmar or plantar osteochondral fractures are not uncommon. Most osteochondral fractures occur on the palmar or plantar aspect of the middle phalanx, either lateral or medial to the axial midline (Fig. 94-1). These fractures do not involve the insertion of SDF tendon or distal sesamoidean ligaments and therefore do not distract. Despite the size and intra-articular location of these fragments, development of osteoarthritis is relatively slow. Nevertheless, they have been reported as a cause of lameness, and surgical removal is recommended if a lameness examination confirms the mid-phalangeal region as the site of pain. They can be incidental findings.

Surgical removal of palmar or plantar fragments using arthroscopy is recommended, although open approaches through the digital sheath are described. The arthroscopic portal is made into the voluminous palmar pouch of the proximal interphalangeal (PIP) joint (Fig. 94-2). Access for instruments is provided by a second portal 2 cm distal to the arthroscope, and often an additional portal on the contralateral side of the palmar region of the pastern, especially when removing large palmar fragments. Fragment dissection and removal can be difficult.

Dorsal fragments also can be removed arthroscopically with an approach over the dorsal joint pouch. Limited maneuverability results from the attachment of the extensor tendon immediately distal to the joint. Arthroscopic entry is usually abaxial to the extensor tendon. The prognosis after surgical removal of dorsal and palmar fragments is favorable, unless the fragmentation is associated with early joint degeneration.

Palmar or Plantar Eminence Fractures
Fractures of the palmar or plantar eminence of the middle phalanx can be uniaxial or biaxial. The treatment and
prognosis vary considerably depending on this configuration. These fractures result from hyperextension of the pastern joint, with tension on the palmar or plantar attachments of the SDF tendon or the distal sesamoidean ligaments. Uniaxial fracture does not result in pastern subluxation or the considerable lameness associated with biaxial fracture. Occasionally, fracture fragments do not involve the entire eminence. Rarely, the palmar soft-tissue structures are disrupted without fracture of the bony insertion. Radiographs verify the type and extent of the fracture.

Uniaxial palmar or plantar eminence fractures can be treated with screw fixation or pastern arthrodesis, depending on the duration and configuration of the fracture.\(^7\) Screw fixation in lag fashion can be performed through stab incisions over the proximal extremity of the fractured eminence, with the screws inserted under radiographic control. Fracture reduction can be difficult depending on the duration of the fracture. The interfragmentary screw is inserted in a distal axial direction, with the primary access to the eminence gained by splitting the insertion of the SDF tendon longitudinally. A delay in presentation or the presence of biaxial palmar eminence fractures necessitates pastern arthrodesis. Even with stable articulations and uniaxial eminence fracture, arthrodesis can be preferable and is best performed using two parallel 5.5-mm cortex screws inserted in lag fashion in addition to a three-hole narrow dynamic compression plate (DCP) dorsally\(^8\) (see Chapter 85). The 5.5-mm cortex screws provide more rigid fixation than 4.5-mm screws. A bone graft is not usually necessary, although forage of the subchondral bone of the proximal and middle phalanx is used to improve access to bone-forming cells.

A postoperative cast is usually maintained for 10 days to 2 weeks. The prognosis after arthrodesis for uniaxial fractures is fair to favorable.\(^2,8,10\) The outlook for return to active work is improved with fractures of hindlimb versus forelimb eminences. Recuperative periods of up to 12 months are required, which can be shortened by the use of plate fixation for pastern arthrodesis.

Biaxial fractures of the palmar or plantar eminences result in considerable lameness and instability of the PIP joint (Fig. 94-3). Pastern arthrodesis by dorsal plate application is preferred.\(^5,12\) Plate configurations include a single broad DCP or two narrow DCPs placed on the dorsal aspect of the proximal and middle phalanges.\(^1,10\) The palmar or plantar eminence fractures are stabilized by screw fixation placed in lag fashion through the distal plate screw holes (Fig. 94-4). Individual interfragmentary screws unassociated with the

Rongeurs have been introduced through an ipsilateral portal adjacent to the palmar condylar surface of the proximal phalanx (PP). B, After removal of the fracture fragment, the fracture bed on the proximal aspect of the middle phalanx (MP) is evident.
plate can occasionally be added to strengthen the repair. Pastern arthrodesis by plate fixation without attempted perfect reduction of the individual eminence fractures is satisfactory; however, callus production and induced secondary lameness are minimized if the eminence fragments can be incorporated into the repair.

Prognosis after biaxial eminence fracture repair by arthrodesis is fair, particularly for fractures involving the hindlimbs.2,8 For additional information on pastern arthrodesis, see Chapter 85.

Axial Fractures
Simple axial fractures of the middle phalanx occur rarely (Fig. 94-5). These fractures can be repaired with cortex or shaft screws applied in lag fashion. The fracture configuration dictates the approach. Adequate reduction is confirmed radiographically before placement of the first screw. Cast fixation during the initial 4 postoperative weeks is important. The prognosis is guarded for ambulation free of lameness because some proliferative new bone formation, especially at the articular margins, is expected as a result of the initial trauma.

Comminuted Middle Phalanx Fractures
Comminuted fractures are the most common configuration of middle phalangeal fracture.5,4 Clinical appearance includes severe non-weight-bearing lameness with palpable instability and, occasionally, crepitus of the distal limb. The configuration of the fracture is confirmed with radiography, and the treatment is selected based on the extent of the fracture and possibility of adequate repair. Treatment options include screw fixation in lag fashion of minimally comminuted fractures, application of a single broad DCP or two narrow DCPs for fracture fixation and pastern arthrodesis, or application of a transfixation cast; another option is euthanasia.

An extensive series of preoperative radiographs is required to establish the extent of comminution. Most comminuted fractures involve proximal portions of the phalanx, and many extend into the distal interphalangeal (DIP) joint, reducing the prognosis (Fig. 94-6). A computed tomographic (CT) scan is particularly helpful in defining multiple fracture planes entering the DIP. Most are more complex than suggested by plain radiographs.

The aim of surgical repair is reconstruction of the distal and, to some extent, the proximal articular surfaces of the middle phalanx. If reconstruction of the DIP joint is inadequate or the bone is severely comminuted and unlikely to be adequately repaired with a plate and screws, humane destruction should be considered.

The most frequent configuration of comminuted fractures involves fractures in both a sagittal and frontal (transverse) plane, often with added comminution on the palmar or plantar proximal aspect. Marked instability because of
involvement of the attachments of the palmar or plantar ligaments and tendinous structures is common. Rarely, the distal sesamoid bone is also fractured. Treatment for most comminuted middle phalanx fractures involves application of two narrow DCPs, although use of a single broad DCP and a T-plate has been described.

Plate fixation in combination with pastern arthrodesis optimizes the chances for adequate reconstruction of the distal articular surface. An extensive dorsal approach to the proximal and middle phalanx is used. The application of two narrow DCPs allows greater versatility in screw placement than a single plate.

The proximal articular surface of the middle phalanx is exposed to allow initial reduction and stabilization of the palmar or plantar portions of the fracture to the dorsal struts of bone. The sagittal fractures are reduced later with individual screws inserted in lag fashion. Intraoperative radiographs ensure reconstruction of the articular surface within the DIP joint.

The cartilage of the PIP joint is removed, and the plate screws in the proximal phalanx are implanted. If possible, one or two plate screws should be placed transarticularly (Fig. 94-7). Postoperative cast fixation for 4 to 8 weeks is used, particularly where fracture stability is tenuous. Follow-up radiographs at the time of cast removal dictate the period of stall confinement, which is an additional 6 to 12 weeks. Postfixation callus development can be extensive, depending on the extent of fracture line reduction and rigidity of the stabilization. The union of the proximal and middle phalanges usually progresses quickly. The most common cause of persisting lameness is osteoarthritis of the DIP joint.

Repair of severely comminuted fractures with cast or transfixation cast techniques is reserved for fractures that cannot be adequately reduced and stabilized by implants and when humane destruction is not an option for the owner. Fractures entering the DIP joint usually result in some osteoarthritis, and the degree of residual lameness varies accordingly. The prognosis is partly determined by the development of weight-bearing laminitis on the opposite limb. The selection of fixation should provide the earliest return of comfortable weightbearing on the fracture to minimize this complication.

Complete resolution of lameness with implant fixation can occur; however, residual lameness is anticipated if there is inadequate reduction of the fracture fragments entering the DIP joint. Concurrent fractures of the distal sesamoid bone reduce the prognosis further. The vascular supply to the distal limb and the soft tissue integrity can occasionally be compromised through the initial fracture or during attempts at repair. Preoperative immobilization in a supporting splint is important for the long-term outcome of these cases (see Chapter 78). Infection can also be a serious complication, and local and systemic antibiotics are used to minimize bacterial growth. The prognosis is improved by the use of a pair of narrow DCPs, and this technique is recommended over others.
Osteoarthritis of the PIP joint (high ringbone) is a relatively common condition affecting multiple breeds, particularly those with a tendency for short upright pastern conformation. In addition, horses that make quick stops and hard turns with rapid twisting, such as Western performance horses and show jumpers, have a high incidence of pastern osteoarthritis. In young horses, there is also the possibility of arthritic change induced by osteochondrosis (OC).

Osteoarthritis can occur in the PIP joints of the forelimbs and hindlimbs and often results in grade II to III/IV lameness. Palpable enlargements of the PIP joints are a feature after the development of periarticular new bone. Confirmation of the PIP joint as a site of lameness usually requires perineural anesthesia and radiographs to confirm the involvement of the joint. Nonarticular new bone production can be misdiagnosed clinically as true intra-articular osteoarthritic change and should be assessed with radiography before any discussion of surgical therapy. Pain on manipulation of the PIP region is occasionally elicited, and the horse can have a positive response to flexion tests of the distal limb. Heat and swelling over the PIP joint are indicators of pastern arthritis. The lameness is usually chronic and exacerbated by increased work. Radiographic evidence of osteoarthritis can be confined to one limb but occasionally occurs in both, if the problem is conformational in origin.

Treatment of true intra-articular PIP osteoarthritis is usually surgical fusion of the involved joint. The response to intra-articular medication with corticosteroid preparations is usually short term. Horses improve considerably with phenylbutazone therapy. Recalcitrant lameness is treated with surgical fusion of the PIP joint. For simple arthritic conditions, this can be accomplished by dorsal exposure of the affected joint, removal of articular cartilage, and application of two 5.5-mm cortex screws to provide lag screw compression across the articulation, as previously described. Additionally, a three-hole plate is applied to the dorsal aspect of the two phalanges involved. Postoperative cast fixation is needed for up to 2 weeks after arthrodesis. Cast bandage combinations may be substituted for the cast in the second week of the 2-week coaptation period.

The rate at which bone union is achieved depends on the degree of stability afforded by internal stabilization. Most horses continue to form periarticular callus for 6 months after surgical repair. Unstable repairs result in exuberant callus, which can interfere with the action of the flexor tendons on the palmar or plantar surface of the pastern and occasionally with the extensor tendons over the dorsal middle phalanx region. Digital extensor tendons can adhere to exostoses on the dorsal aspect of the distal phalanx and
result in residual lameness. Excessively long screws that penetrate the palmar or plantar surface of the middle phalanx and interfere with the action of the distal sesamoid bone are causes of residual lameness.

The prognosis for riding soundness is fair to favorable, particularly for conditions involving the hind limb. The outcome in one report indicated 16 of 22 horses returned to full function. A second study indicated 16 of 21 clinical cases became sound after arthrodesis, with a better response in the hind limbs.

**Osteochondrosis and Subchondral Cystic Lesions**

OC can occasionally develop in the PIP joint. Subchondral cystic lesions (SCLs) are diagnosed more often than dissecting cartilage flap lesions and involve the distal articular surface of the proximal phalanx (Fig. 94-8) or rarely the proximal articular surface of the middle phalanx. Late stages of OC with secondary osteoarthritis have been diagnosed in young horses unilaterally and bilaterally. Solitary SCLs are readily apparent on radiographs, whereas multiple SCLs are associated with a persistent lameness leading eventually to osteoarthritis.

Intra-articular hyaluronan injections provide temporary pain relief in solitary SCLs. Surgical curettage of solitary SCLs of the proximal phalanx has been performed in five horses (three foals and two adults). Because the lesion is often not approachable arthroscopically, transosseous drilling is used. Initially, a small drill bit is advanced under fluoroscopic control into the cyst, confirmed by draining of saline previously injected into the PIP joint. Proper seating of the drill is verified radiographically, and the drill hole is enlarged with a 5.5-mm drill bit, allowing access with a curet to evacuate the cyst. After copious flushing from the joint, the cyst and drill hole are filled with tricalcium phosphate granules. Long-term follow-up revealed that four of the five horses treated were serviceable and could engage in the intended athletic function. Additional information about this treatment is found in Chapter 92.

Multiple cystic lesions show a poor response to medical treatment, leaving elective arthrodesis of the joint as the only treatment (see Chapter 85). Simultaneous bilateral arthrodesis can be performed in foals, whereas staged fusion is elected in adult horses.

**Luxation and Subluxation**

Luxation and subluxation of the PIP joint are usually treated with arthrodesis. Subluxation is more common and occurs in either a dorsal or palmar direction. Dorsal subluxation is the result of damage to the suspensory ligament and its terminal extensor branches; it can occasionally be caused by contracture of the distal sesamoidean ligaments (Fig. 94-9). Palmar subluxation results from failure of the palmar ligament.
supporting connective tissues such as the distal sesamoidean ligaments and SDF tendon insertions.

This condition is manifest by marked hyperextension of the PIP joint and considerable swelling associated with the soft tissue disruption. The clinical signs associated with dorsal and palmar subluxation include acute lameness initially, with the dorsal subluxations resulting in an obvious dorsal swelling over the PIP joint. Palmar subluxation, because of disruption of the support structures, usually results in hyperextension of the pastern and sinking of the metacarpophalangeal (MCP) joint. Radiographic examination is used to confirm the diagnosis of subluxation and to differentiate lesions associated with osteoarthritis or bony disruption of the middle phalanx. The lameness associated with PIP subluxation is less severe than that associated with fracture disruption.

Dorsal subluxation occurs bilaterally in the hind limbs of some horses with upright conformation. When this occurs, it can be managed with anti-inflammatory medication and a controlled exercise program. As the horse gains condition, the subluxations resolve.

Pastern arthrodesis is used to treat recalcitrant dorsal and palmar subluxations. Surgical arthrodesis is performed using either the slightly diverging lag screw technique or, preferably, the application of a single bone plate or a pair of bone plates as previously described. Some acquired dorsal subluxations are caused by excessive tension in the deep digital flexor (DDF) tendon, and successful resolution in three hindlimb cases resulted from release of the medial head of the DDF tendon.16

The prognosis after repair of subluxation is fair to favorable. With adequate reduction of the subluxation and stabilization, the pastern can be fused without excessive callus formation. Few cases are described in the equine literature that provide information on long-term follow-up, but horses can return to athletic activity, particularly if a hindlimb is involved. Rarely, bilateral subluxations develop, and a staged pastern arthrodesis can provide a return to soundness.

**PROXIMAL PHALANX**

Fractures of the proximal phalanx can be divided into two categories: proximal intra-articular osteochondral fractures and fractures involving the shaft or diaphyseal region of the proximal phalanx. The cause of most of these fractures is trauma, with hyperextension being particularly important for osteochondral fractures, and torsion with axial weight-bearing being more important for fractures of the shaft of the proximal phalanx.

**Proximal Osteochondral Fractures**

**Proximodorsal Osteochondral Fractures**

Osteochondral fractures of the proximal dorsal margin of the proximal phalanx within the MCP joint are common in racehorses.17 They arise from hyperextension of the MCP joint with impact of the phalanx onto the dorsal region of the third metacarpus (MCHI). Proximodorsal fragments in immature horses have been described as OC, but it is uncommon to find histologic evidence to support these claims. Initial clinical symptoms include several days of moderate lameness associated with obvious synovial effusion and pain on flexion of the affected joint. Depending on the size of the fragment, lameness dissipates quickly. Radiography with four views, including horizontal beam oblique views, demonstrates the lesion adequately. The most prevalent site is the proximal medial eminence of the proximal phalanx. Occasionally, both lateral and medial eminences of the phalanx are involved.

The treatment of choice is surgical removal using arthroscopy.17 However, small chip fractures (less than 2 mm in diameter) can be rapidly covered by synovial tissues, and many heal without causing clinical symptoms. Moderate to large dorsal fragments should be removed to prevent synovitis, cartilage degeneration, and villonodular synovitis mass development. Large chip fractures result in erosion of the opposing metacarpal condyle and often result in persistent lameness.

The arthroscope is placed into the joint just proximal to the middle of the dorsal joint pouch, next to the extensor tendon, because this facilitates examination of both lateral and medial portions of the joint without damage to the dorsal aspect of the sagittal ridge. A second entry portal is then made for instrument entry and fragment retrieval.

Postoperative convalescence includes 6 to 12 weeks’ rest from race training, depending on the damage to the metacarpal cartilage. Results of arthroscopic surgery for the treatment of osteochondral fractures of the proximal phalanx in 336 horses revealed a return-to-use rate of 86% for racehorses.18 Additionally, 68% of horses returned at the same or higher level of race performance. Removal of osteochondral fractures also may be useful even when moderate levels of osteoarthritis are present. Seventy-five percent of horses with other MCP lesions, including arthritis, were able to return to previous use.

**Proximopalmar and Proximoplantar Osteochondral Fractures**

Bone fragments associated with the plantar or palmar portions of the proximal phalanx within the metatarsophalangeal (MTP) or MCP joint have been recognized for many years.19,20 The cause of fragmentation is controversial; one suggestion is that they are OC lesions. Recent data support a fracture etiology.21

The osteochondral fragments have been categorized as type I fractures when they are avulsed from the axial, proximal palmar, or plantar rim of the proximal phalanx and are mostly articular. Larger, abaxially located, partly articular osteochondral fragments have been categorized as type II fractures. Type II fractures extend distally 2 to 3 cm and contain minimal articular cartilage. Lameness associated with type I fractures is minimal and usually evident at higher speeds.22,23 Type II fractures do not appear to produce lameness.

Affected MCP or MTP joints often exhibit synovial effusion, moderate pain on flexion, and a mild to moderate response to flexion tests. Intra-articular anesthesia is often required to confirm the diagnosis. The fragments are uncommon in the forelimb, possibly as a result of a more angled shape to the equine palmar aspect of the proximal phalanx compared with the plantar counterpart. Fragments have occurred in weanlings and yearlings, presumably as part of a form of OC.22,24 Because most occur in younger
animals, they are often covered by synovial tissue at the time of surgical removal. They are most prevalent in Standardbreds; 11.8% of all Standardbred yearlings in Norway26 and 28.8% of yearlings in Sweden are affected.26 In Warmblood horses, these lesions are diagnosed in 3- to 6-year-olds, when the training level for show jumping is increased.

Radiography is used to confirm the diagnosis. Routine oblique views are not particularly satisfactory for delineating type I fractures. A better projection results from raising the radiographic beam 20 degrees above horizontal and taking the oblique projections only 15 to 20 degrees dorsal to a standard lateromedial projection (Fig. 94-10).27 These projections allow differentiation of type I axial fractures of the plantar aspect from the type II abaxial fractures (nonunited proximal plantar tuberosity of the proximal phalanx).28,29 Type II fractures are quite evident on standard oblique radiographs. Both types of fragments are common in the MTP joints.

Type I plantar fractures are often removed in yearlings to prevent the development of lameness during training and racing. Lameness in yearlings is uncommon, and the prediction of later lameness induced by these plantar fragments is difficult. An arthroscopic approach through the plantar pouch of the MTP joint provides access to the intra-articular type I fractures.30 The instrument portal is made at the base of the proximal sesamoid; the exact location of the portal is identified with a hypodermic needle. The fragments are dissected from the covering of synovial membrane and remnants of the attached short sesamoidean ligaments and removed with sturdy rongeurs. The use of motorized resectors, radio-frequency cutting loupes, or laser for removing excessive soft tissue proliferations and resection of the fragment reduces intraoperative bleeding and improves visualization.

Surgery is rarely indicated for type II abaxial osteochondral fractures. Additionally the incidence of these fragments is lower (2.4% of 753 Standardbred yearlings),27 and they might not be fractures but rather might constitute a form of delayed ossification. Lesions in 11 of 18 horses had radiographically united to the parent proximal phalanx after 12 months. Occasionally nonhealing abaxial “fractures” and true traumatic fractures with fresh margins and associated lameness require screw fixation in lag fashion to achieve radiographic union. This type of fixation is only warranted when lameness is present, and simple absence of progressive bony fusion is not a cause for surgical fixation.

Convalescent care for type I fracture patients includes 6 to 12 weeks’ rest from race training, depending on the damage to the distal sesamoidean ligaments at the time of surgery. In a review of 119 surgery cases, follow-up race performance information was available on 87.23 Fifty-five horses (63%) returned to racing at or above their preoperative level. Abnormal arthroscopic findings with a negative impact on successful outcome included horses with articular cartilage loss over the palmar condyles and those with synovial proliferation.

Dorsal Frontal Fractures of the Proximal Phalanx

Dorsal frontal fractures entering the MCP joint are relatively rare; in a case series, they represented only 9 of 123 (7%) fractures involving the shaft of the proximal phalanx.16 These fractures occur predominantly in Thoroughbreds and are prevalent in the hindlimbs. Dorsal frontal fractures tend to be short, extending from the articular surface 2 to 5 cm distally in the dorsolateral cortex of the proximal phalanx. Fractures are generally complete and minimally displaced. Fracture configuration and degree of displacement dictate the need for surgical repair.

Complete fractures are better repaired using screw fixation in lag fashion, although nondisplaced fractures heal with conservative therapy.8 Complete and displaced fractures should be repaired with interfragmentary screws. The surgical repair can be supplemented by arthroscopic examination of the dorsal intra-articular region of the affected joint and debridement of associated cartilage damage. Insertion of one or two 3.5-mm cortex screws using the lag screw technique is recommended (Fig. 94-11).

Most horses recover in a soft bandage. Two weeks of complete stall rest is followed by 6 weeks of limited daily hand-walking. The implants are removed only where lysis or reaction has developed, associated with the screw heads. If conservative therapy is selected, adequate radiographic healing of the fracture occurs in 4 to 6 months.8 The prognosis for a return to racing is favorable, with 6 to 9 horses reported to have returned to satisfactory performance with nonsurgical therapy.

Diaphyseal Fractures

Most axial fractures of the proximal phalanx occur in the sagittal plane and propagate distally from the articular surface of the MCP joint. The mid-sagittal groove is mecha-
better demonstrate the fracture. Short sagittal fractures are proximodistal and distoproximal dorsopalmar projections, photographs. Several different dorsopalmar projections, using can be difficult to localize on routine dorsopalmar radiographs. A interphalangeal joint (Fig. 94-12, A). Short sagittal fractures originate in the sagittal groove and extend distally. Complete fractures exit on either the lateral or, rarely, medial cortex of the proximal phalanx or enter the proximal cortex of the proximal phalanx or enter the proximal interphalangeal joint (Fig. 94-12, A). Short sagittal fractures are difficult to isolate through a routine lameness examination. The use of desensitizing nerve blocks in this configuration increases the risk of propagation of the fracture. Affected horses show moderate pain of relatively short duration with incomplete sagittal fractures. Fractures extending the full length of the proximal phalanx and those that tend to comminate result in non–weight-bearing lameness and moderate swelling of the pastern. Short, incomplete proximal fractures of the phalanx are sometimes difficult to isolate through a routine lameness examination, and perineural anesthesia is necessary to localize the site of lameness. The use of desensitizing nerve blocks in this situation increases the risk of propagation of the fracture lines during the lameness examination.

Radiographs define the extent of the fracture; most fractures commence in the sagittal groove and extend distally. Complete fractures exit on either the lateral or, rarely, medial cortex of the proximal phalanx or enter the proximal interphalangeal joint (Fig. 94-12, A). Short sagittal fractures can be difficult to localize on routine dorsopalmar radiographs. Several different dorsopalmar projections, using proximodistal and distoproximal dorsopalmar projections, better demonstrate the fracture. Short sagittal fractures are not considered with the owner of the horse. Therefore, pastern arthrodesis should be considered or at least discussed with the owner of the horse.

Postoperative support is provided using fiberglass casts or splints. Follow-up radiography is used to assess bone union, and most horses can return to light training 4 months after repair. Proximal phalanx fractures of the hindlimb are

**Figure 94-11.** Dorsal frontal fracture of the dorsolateral cortex of the proximal phalanx in the rear limb. Repair using two 4-mm cancellous screws has resulted in improved joint congruity.

**Surgical Techniques**

**NONDISPLACED FRACTURES**

For routine nondisplaced fractures, the proximal phalanx can be stabilized by insertion of screws in lag fashion through stab incisions (see Fig. 94-12, B). The most proximal screw in the series preferably should be a 5.5-mm cortex or shaft screw for additional compression of the articular surface, although 4.5-mm screws are adequate. Intraoperative radiographic monitoring is recommended to ensure that the proximal screw does not penetrate the MCP joint and the fracture planes are being adequately compressed.

Ideally, the proximal screw should pass within 5 mm of the most distal point of the sagittal groove of the proximal phalanx to provide maximum compression to the articular surface. This screw should penetrate the transcortex, and the screw head should be adequately countersunk to avoid torque on the screw shaft from the oblique angle of the cortex beneath the head. Additional screws are placed at intervals of 20 to 22 mm until the entire fracture line has been stabilized.

A less common configuration involves fractures in a frontal plane. These fractures can be repaired similarly, placing screws in a dorsolateral to palmar direction. However, in this configuration, potential trauma to the distal sesamoidean ligaments by sharp fragments can result in subluxation of the proximal interphalangeal joint after fracture healing. Therefore, pastern arthrodesis should be considered or at least discussed with the owner of the horse.
more likely to require cast support for the recovery phase because of increased torsional loads on the hindlimbs during recovery. Implant removal is unnecessary for fractures of the proximal phalanx. Lysis beneath the screw head, drainage from the wound, or excessively long screws are indications for screw removal.

MILDLY TO MODERATELY DISPLACED FRACTURES
Complete fractures that involve sagittal and oblique fracture planes with mild to moderate displacement can generally be better reduced with open approaches to the proximal phalanx followed by screw stabilization using lag technique. Access for fracture débridement and reduction is provided by an incision over the dorsal aspect of the sagittal fracture. The incision usually enters the MCP joint for direct inspection of the articular surface, particularly to ensure accurate realignment of the subchondral bone plate and overlying cartilage. More extensive fractures require a more extensive longitudinal incision. Separate stab incisions are used for placing the screws in lag fashion in a lateral plane to stabilize the sagittal fracture.

Extensive fractures that have multiple sagittal and frontal plane fractures require an extensive open approach either using an L-shaped incision that exposes the entire dorsal and abaxial cortices of the proximal phalanx or an S-shaped incision. The latter approach involves severing a collateral ligament of the MCP joint to expose the proximal articular surface of the proximal phalanx. The exposure of the fracture planes and the proximal articular surface allows placement of interfragmentary screws in lag fashion in multiple directions to anatomically reconstruct the bone around the residual intact strut. Most screws are placed in a lateromedial or dorsopalmar direction to provide stabilization of sagittal and frontal fracture planes, respectively. Alternatively, using the dorsal L-shaped incision, the dorsal articular margin of the proximal phalanx can be evaluated during screw insertion, and intraoperative radiographic control is used to ensure the remaining fracture planes are adequately aligned during reduction and stabilization (Fig. 94-13). This preserves the collateral ligaments and the metacarposesamoidean ligaments.

The limb is cast to the proximal aspect of MCIII or MTIII for recovery from anesthesia and for the next 6 weeks. Radiographic evaluation is then used to determine whether additional cast time is required. Preoperative antibiotics are continued for 3 to 5 days after surgery to minimize the risk of sepsis. Intraoperative culture during extensive and prolonged procedures might also be useful before closing the soft-tissue structures.

SEVERELY COMMUNICATED FRACTURES
Fractures without an intact strut of bone are poor candidates for internal fixation. These fractures are generally high-energy fractures and the bone is extensively fragmented...
Lameness is marked, and considerable swelling can develop if the limb is left unbandaged for any length of time. Extensively comminuted fractures need to be stabilized within a cast before transfer of the horse for evaluation and surgery. Radiographs can often be taken through the cast to define the fracture configuration and the possibility for surgical repair or humane destruction. For cases where repair is desired, transfixation casts usually provide a reasonable possibility of salvaging the horse. Return to athletic activities is not an option.

Simple cast fixation does not provide resistance to axial collapse of the fracture within the cast. The complications of collapse include continued lameness, a high risk for development of pressure necrosis of the skin leading to an open fracture, and laminitis of the unaffected weight-bearing limb. Transfixation techniques reduce the collapse of the fracture within the cast by using transcortical pins in the distal portion and mid portion of the MCIII or MTIII. Pins with positive threads located in the center are preferable, and preparing the threads in the hole with a suitably sized tap is generally required before the pin is inserted (see Chapter 81).

An alternative to transfixation cast is the Nunamaker external skeletal fixator, which uses a series of transfixation pins through the MCIII or MTIII joined to side-connecting bars attached to a foot plate (see Chapter 81). The most significant complications of transfixation casts and the external skeletal fixator is ring sequestrum formation around the pin tracts, especially in heavy horses, and subsequent fracture through a pin hole. However, this fixator is a good choice for salvaging horses with massively comminuted fractures.

**THE METACARPOPHALANGEAL JOINT**

**Palmar Metacarpal Fragmentation**

Palmar fragmentation of the metacarpal condyles is a trauma-induced disorder, which results from the accumulated stress and sclerosis that develops during racing. Previously, this disease was thought to be OC of the palmar or plantar surface of the MCIII condyles. However, there are no histologic data to verify this etiology, and classification as an OC lesion has been abandoned. Most patients are Thoroughbred racehorses that are 3 years old or older and have moderate to severe MCP lameness.

The palmar lesions are identified on standard lateromedial and flexed lateromedial projections (Fig. 94-15). Additional information can occasionally be derived from 125-degree dorsopalmar projections. The radiographic lesions appear as different shapes including crescent, flat-
tended, concave, oval, or circular. Secondary arthritic changes are common, with periarticular osteophytes or enthesiophytes, narrowing of the joint space, and supracondylar lysis. A prominent secondary feature is intense sclerosis of the palmar region of the condyle, deep to the lytic region. Morphologic assessment of these degenerate metacarpal condyles indicates an area of acellular and apparently necrotic bone over the entire distal palmar region of the affected metacarpus. Deep to the necrotic area is a zone of new bone formation producing a sclerotic barrier that compensates for the biomechanical dysfunction of the palmar fracture. These remodeling and fracture changes are the result of accumulated stress fractures in the palmar region of the condyle, largely as a result of hyperextension of the MCP joint. Early lesions may have little overlying cartilage damage; however, eventual fracture and displacement of the subchondral bone result in complete bone and cartilage loss (Fig. 94-16). Lameness, although initially mild or moderate, then becomes severe.

Scintigraphy is sensitive in detecting the early stress fracture and bony deposition forming the sclerotic zone within the palmar region of the condyle. This is particularly helpful because the sclerosis can be reduced or allowed to remodel rather than progress to palmar fracture with prominent symptoms. This condition is difficult to treat, and efforts at prevention are important. Access to the palmar region of the distal metacarpus is very limited and is made more difficult because most of these lesions are close to the transverse ridge.

Proximal Sesamoid Bone Fractures

Fractures of the proximal sesamoid bones are relatively common, particularly those involving the apical portion. Other configurations include basal, midbody, abaxial, sagittal, and comminuted fractures (Fig. 94-17). Most proximal sesamoid fractures occur because of excessive tension on the suspensory apparatus. Apical fractures are particularly common in the hindlimbs of Standardbreds, and the resultant prognosis often is dictated by the extent of loss of suspensory ligament insertion and pre-existing suspensory desmitis. All except abaxial, nonarticular fractures result in MCP effusion and moderate to severe lameness of short duration.

Apical fractures involving the proximal one fourth to one third of the proximal sesamoid bone are always articular; however, they do not result in extensive suspensory derangement, and lameness diminishes rapidly. Removal of apical fragments up to one third of the proximodistal dimension...
of the proximal sesamoid bone is recommended, although better results are evident with smaller apical fractures, where there is less disruption of suspensory ligament insertion. Removal of the proximal third of the proximal sesamoid bone results in delay of return to racing and a considerably reduced likelihood of a successful postinjury career.

Arthroscopic removal of apical fractures results in less-extensive dissection and secondary fibrosis, but large apical fragments are best removed through arthrotomies. The arthroscope is inserted in the proximal aspect of the palmar or plantar pouch, and the instrument portal is made at the level of the fracture, allowing dissection of the fragment from the suspensory attachment.

Midbody and basal fractures present special problems for surgical fixation. Both of these injuries are slightly more prevalent in Thoroughbreds, and internal fixation is required for adequate fracture union. Midbody proximal sesamoid fractures should be repaired with either circumferential wiring or lag screw fixation. Previous therapy, including bone graft and extended periods of cast fixation, is unreliable in returning horses to work.

When circumferential wiring is used, either two separate approaches are made to access the lateral and medial aspect of the sesamoid bone or a combined, laterally based C-shaped incision is made that is centered over the sesamoid bone. The tendon sheath is opened palmarly, and a 2.5-mm drill hole is prepared across the apex. The drill bit is oriented parallel to the base of the bone in a slightly dorsopalmar direction. Exiting of the drill bit is observed through the open tendon sheath. A 14-gauge, 5-cm-long needle is placed into the hole. The beveled edge must be visible in the tendon sheath. Another 14-gauge hypodermic needle is placed laterally along the base of the fractured bone. A 1.2-mm-diameter wire is passed through the first needle, directed distally within the tendon sheath, and introduced into the pointed end of the second needle. By advancing the wire and retracting the second needle, the wire is exited at the lateral aspect of the bone. The proximal end of the wire is tunneled along the lateral aspect of the bone to the exiting point of the distal end of the wire, where the two ends are tightened solidly through even twisting using the Fastight (Synthes, Paoli, Penn) wire tightener. Excess wire is cut with a pair of cutters, and the end is turned toward the bone to reduce irritation of the surrounding soft tissues. The tendon sheath and soft-tissue incisions are closed using routine technique.

Screw fixation in lag fashion is performed from the base or the apex of the bone, depending on the configuration of the fracture. An oblique fracture with the fracture plane declining from medial to lateral is best treated with an interfragmentary screw placed from the apex, whereas a fracture declining from lateral to medial is best approached from the base. Interfragmentary compression and reduction during screw insertion is maintained with large pointed reduction forceps. Frequent intraoperative radiographs are essential for a high-quality repair. The screw head should come to lie between the oblique and straight distal sesamoidean ligaments in a natural fossa of the proximal sesamoid bone in the base approach, or proximolaterally at the apex of the bone, embedded in the insertion of the lateral suspensory branch. Insertion technique for the screws is routine once the correct screw position has been verified radiographically. Circumferential wiring and interfragmentary screw fixation in lag fashion return up to 60% of horses to active racing.

Basal slab fractures involve the origin of all the distal sesamoidean ligaments, and the prognosis is certainly unfavorable. Lag screw fixation is rarely suitable because of the thin fragment profile, and the only recommended treatment has been circumferential wiring. There is an inverse relationship between fragment length and height and the likelihood of return to racing. Basal osteochondral fragments that do not extend to the palmar surface have a much better prognosis, with 59% returning to racing in a recent study of 57 horses. Many of these fractures can be removed arthroscopically. Similarly, in a second study, 57% of horses with fragments involving less than 25% of the base successfully returned to racing after fragment removal, compared to 40% with fragments involving more than 25% but not the entire base.

Abaxial fractures must be assessed by a 60-degree skyline projection of the abaxial surface of the proximal sesamoid, which demonstrates whether the abaxial fracture is intra-articular or palmar and not involving the joint (Fig. 94-18). Intra-articular fractures can be removed arthroscopically, whereas the nonarticular fractures are best treated conservatively. Return to function is fair to good (61%), depending on the length of the intra-articular fracture.

Sagittal fractures are rare and tend to occur on the axial margin of the sesamoid bone in conjunction with other MCP injuries such as condylar fractures (see Fig. 95-5). Very rarely, they can develop as isolated fractures, but they

Figure 94-18. Elevated 60-degree lateromedial projection (Pr60L-DiMO) of the proximal sesamoid bones to evaluate the intra-articular component of an abaxial sesamoid fracture (arrow).
can be repaired using several lag screws placed in a lateral-
to-medial orientation. Postoperatively, application of a cast 
is recommended for the initial 2 to 3 weeks. At that time, if 
everything looks satisfactory, the cast is exchanged for a 
heavy support bandage. The remainder of the postoperative 
management is routine.

Comminuted and biaxial fractures are severe breakdown 
injuries involving the MCP joint. In most cases, these horses 
require fetlock arthrodesis for a return to comfortable 
weightbearing68 (see Chapter 85) (Fig. 94-19).

Follow-up on 109 horses with apical sesamoid fractures 
indicated that 64% of the horses treated surgically raced 
later,66 whereas only 37% of those treated conservatively 
raced again. For midbody fractures repaired with lag screws, 
9 of 12 horses were able to race after surgery.69 Similarly, in 
horses with midbody fractures repaired by wiring, 11 of 15 
were able to resume an athletic career, with half of these 
performing at the same level or better than before the 
injury.70

Chronic Proliferative (Villonodular) Synovitis

Development of soft-tissue masses in the dorsal aspect of 
the MCP joint is common secondary to chronic synovitis.57-
61 The most frequent cause is dorsal proximal phalangeal 
osteochondral fractures that are not immediately treated 
by fragment removal. In addition, villonodular masses com-
monly develop with advancing osteoarthritic changes within 
the joint. Horses with long pasterns are predisposed to this 
problem. A visible and palpable mass is evident in the 
proximal dorsal region of the affected fetlock. Lameness is 
usually moderate to moderately severe depending on the 
underlying disease. Radiographs occasionally show cortical 
lysis on the dorsal region of MCIII, under the enlarging 
mass. Definitive diagnosis requires either arthrography or 
ultrasonographic examination.77 Ultrasonography is more 
convenient.

Most masses are 7 to 10 mm in diameter. The minimum 
width that warrants surgery is 4 mm; smaller masses can be 
treated with intra-articular atropine and steroids. The 
enlarged medial portion of the villonodular plica is usually 
 thicker than the lateral portion.

A critical factor in the decision for surgery is the extent of 
osteoarthritis present in the joint. Osteochondral fragments 
and other fracture diseases in the MCP joint result in sec-
ondary fibrous mass development, and these fibrous masses 
can be removed without difficulty and with reasonably 
favorable prognoses.17,60 Masses secondary to osteoarthritis 
are generally larger and more chronic, and the associated 
arthritis dictates the likelihood of successful return to work 
after the mass is removed. A critical evaluation of the joint 
space on preoperative radiographs and the use of ultra-
sonography to measure the dorsal articular cartilage thick-
ness prevent inadvertent operation in these cases.

Primary villonodular masses can develop without an 
obvious initiating factor, and these most likely result from 
hyperextension of the MCP joint and impact trauma on the 
normal synovial plica, which forms a pad or cushion to 
lessen the impact of the dorsal margin of the proximal 
phalanx onto the metacarpal cortex.57,60 Hemorrhage and
fibrosis in this plica eventually result in significant enlargement, which is then more easily and repeatably injured during exercise. This is quite painful, but the horses do very well after surgery to remove the mass.

Arthroscopic approaches are suitable for removal of villonodular masses (Fig. 94-20), although some masses are so large that they require arthrotomy for excision. Arthroscopic visualization allows mass removal using synovectomy instrumentation, guarded scalpels, or the biopsy suction punch for smaller masses (Dyonics, Smith & Nephew, Memphis, Tenn). Large masses can also be efficiently removed using CO₂ or holmium:yttrium-aluminum-garnet (holmium-YAG) laser where access to this equipment is available.

Postoperative therapy includes intra-articular injections of 20 to 40 mg of hyaluronan. Repeat doses in 3 to 4 weeks are recommended. The use of polysulfated glycosaminoglycan (Adequan) is another option depending on the state of the articular cartilage. Return to race training depends on concurrent arthritis.

Osteoarthritis

Deterioration of articular cartilage is common in mature racehorses and can lead to moderate to severe unrelenting lameness, with the development of periarticular osteophytes, enthesiophytes, and joint space collapse, particularly medially. These horses respond poorly to intra-articular medication and require frequent injections to remain comfortable. Collapse of the medial compartment of the MCP joint is more prevalent than the lateral and often indicates the likelihood of a career-ending lameness.

Therapeutic options are limited. Pain relief can be effected by intra-articular steroid administration, but continued cartilage degradation is inevitable. In the final stages of joint deterioration, some improvement in the level of lameness has resulted from the administration of silicone oils to the joint and from desensitization of the synovial capsule with intra-articular cobra venom. The author has no first-hand experience with cobra venom as a form of therapy. Ultimately, some horses need MCP arthrodesis to become comfortable (see Chapter 85).

Osteochondrosis and Subchondral Cystic Lesions

Several manifestations of OC can occur in the MCP joint, and the incidence is relatively high. Two different types of MCP OC lesions are described.

The first are dissecting cartilage flaps (osteochondritis dissecans [OCD]). They appear as mineralizing lesions on the dorsal sagittal ridge of the MCIII or MTIII and are common in young horses 8 to 24 months old. These OCD lesions can affect all four MCP joints. They also appear as palmar metacarpal OCD lesions, which result in a debilitating lameness, often progressing to osteoarthritis and representing the most serious form of MCP OCD. These lesions occur in horses as young as 10 months but are more common in young race-age horses. (Distopalmar metacarpal fragmentation in 3- to 4-year-old racehorses was originally described as OCD, but this is a different disease from that described here as OCD.)

The second type of OC lesions in the MCP joint are subchondral cystic lesions (SCL) of the distal MCIII or MTIII condyle. They occur most commonly in weanlings and yearlings but can be first diagnosed in 2-year-olds in training. The resulting lameness is variable, and occasionally severe, but osteoarthritis is a rare sequela. Most subchondral cysts open to the joint just cranial to the transverse ridge by a narrow communicating channel. Occasionally, multiple cysts are present in the same bone, and the cysts can be bilateral. Cysts of the proximal articular surface of the proximal phalanx also can be seen, often opening near the sagittal groove.

The degree of lameness largely depends on the type of MCP OC. Dorsal sagittal ridge lesions result in mild to minimal lameness, although flexion tests of the involved joints are often positive. The other form of OC and SCL results in more significant lameness. Lameness and pain on flexion are most pronounced with palmar OCD lesions in yearlings. Regardless of the site, MCP effusion is a prominent feature. Most horses have sufficient lameness, synovial effusion, and exacerbation of the lameness with flexion tests that a tentative diagnosis can be reached without regional or intra-articular anesthesia. Radiographs are necessary to determine the exact cause of MCP disease and to provide prognostic guidelines. Dorsal sagittal ridge lesions often manifest as mineralized densities adjacent to the sagittal ridge (Fig. 94-21, A). They often arise from the proximal condylar cartilage and are more correctly termed dorsal parasagittal or dorsal condylar OCD lesions.

Treatment options vary according to the site of involvement. Palmar MCIII and plantar MTIII lesions are relatively inaccessible, and surgical therapy is not possible unless the lesion is located unusually far caudad on the condyles or sagittal ridge. Occasionally, part of these lesions can be debrided under arthroscopic guidance with a palmar or plantar pouch approach. On most occasions, however, the lesions are inaccessible, and osteoarthritis with permanent lameness is the usual sequela. These young horses rarely enter and sustain an athletic career.

Dorsal sagittal ridge and parasagittal condylar lesions should be surgically removed under arthroscopic guidance (see Fig. 94-21, B). The technique as described previously should be applied. These lesions can achieve considerable size, and removal can leave a substantial subchondral defect. However, in this location, joint stability is unaffected, and

Figure 94-20. Arthroscopic removal of an 8-mm villonodular pad from the fetlock using a biopsy punch rongeur.
the outlook remains favorable. Subchondral cystic lesions of MCIII or MTIII that have narrow openings to the joint can be treated successfully with several injections of hyaluronan (Fig. 94-22, A). Most yearlings do well, and the lameness quickly resolves. The cystic cavity generally fills in but may take 1 to 2 years. Occasionally, lameness persists despite intra-articular medication and limited exercise, and surgery should then be considered.

Cystic lesions with wide channels to the articular surface do not respond to conservative therapy nearly as well as cysts with narrow openings, and debridement is often recommended at the initial diagnosis (see Fig. 94-22, B). Surgical débridement of the cysts can be accomplished via dorsal arthroscopy with the MCP joint flexed. Most cysts can be curetted; bone grafts are not usually necessary.

Arthroscopic techniques can be used only with cysts opening on or dorsal to the transverse ridge of MCIII. More palmar cysts are best approached transosseously through drilling. Cysts of the proximal phalanx can be débrided with difficulty from the articular surface, particularly in MTP joints where the joint separates with flexion.

The outlook for a sustained athletic career is favorable for subchondral cystic lesions of the distal MCIII or MTIII, reasonably favorable for dorsal sagittal ridge and parasagittal OCD, and poor for palmar metacarpal OCD flaps.

**Luxation**

Lateral or medial complete luxation of the MCP and MTP joints occurs after rupture of either the medial or lateral collateral ligament. Occasionally, there is an avulsion of the origin or insertion of one of these ligaments, resulting in marked instability. The condition is relatively rare and results primarily from entrapment of the distal limb in holes in the ground or cattle grates. The diagnosis is obvious when an angular deviation can be easily induced on manipulation (Fig. 94-23). Radiography with a dorsopalmar projection with the limb under lateral or medial bending stress usually provides clear evidence of the extent of the luxation. Some injuries associated with trailer accidents result in an open luxation with disruption of the collateral ligament and some loss of bone structure because of pavement injury.

The treatment of closed luxations is simple and involves cast fixation for 6 weeks. Imbrication or repair of the collateral ligament is not usually necessary. The cast is applied with the horse anesthetized, maintaining the lateral–medial stability as the cast cures. Surgery for open luxations is necessary for adequate wound débridement and soft-tissue closure. Extensive antibiotic lavage and removal of all foreign matter are essential. Treatment of the luxation initially in a splint is an option for the acute inflammatory phase, until the infection has been controlled. Later, elective cast application for increased stabilization can be used, or arthrodesis by application of a DCP and screws can be used if the joint surface is extensively damaged (see Chapter 85).

A single case series involving 10 horses is reported in the literature; five horses had open luxation and five had closed luxation. The open luxations were treated with joint lavage and cast immobilization, and the majority were sound at follow-up, including one horse that was being actively ridden.

The development of obvious sepsis within the MCP joint can be minimized by aggressive early therapy and the placement of lavage drains and ingress antibiotic portals. Later application of antibiotic-laden bone cement assists in bringing the infection under control. Overall, the prognosis after the development of infection is guarded, and chronic lameness can be expected. Some of these cases can be salvaged with aggressive débridement and elective arthrodesis later.

**ANGULAR LIMB DEFORMITY OF THE DISTAL JOINT**

Angular limb deformities originating at the distal physis of the MCIII or MTIII develop relatively often in foals; most are varus deformities. Concurrent valgus of the carpus or tarsus and a varus deformity of the MCP region are common. Many varus deformities are congenital and improve during the early postnatal period. A detailed discussion of angular limb deformity is found in Chapter 89.
FLEXURAL DEFORMITY OF THE METACARPOPHALANGEAL JOINT

Flexural deformities of the MCP joint can be classified as congenital or acquired.

**Congenital Deformities**

Congenital deformities are often relatively severe. If they are bilateral, the foal can have difficulty rising or, if it does stand, it tends to knuckle over at the MCP joint (Fig. 94-24). In some congenital cases, tension is apparent in both the deep and SDF tendons; in others, the common digital extensor tendon is ruptured. Occasionally, even the suspensory ligament is taut on palpation.

**Acquired Deformities**

Acquired flexural deformities can be unilateral or bilateral. Both forelimbs are commonly affected, one generally more severely than the other. The pathogenesis of the acquired form of flexural deformity is thought to involve pain-induced reflex loops in the ipsilateral limb, often precipitated by other skeletal disease. The diagnosis and management of these deformities are discussed in detail in Chapter 90.

**ANNULAR LIGAMENT CONSTRICTION**

Chronic tenosynovitis is a relatively common affliction in the digital sheaths of horses, developing mostly in the hindlimbs as an insidious reaction to increased workloads. Most cases of tenosynovitis are successfully treated by changing exercise intensity with or without intrasynovial medication. Untreated tenosynovitis or tenosynovitis associated with more serious disruption of the tendon sheath, the various mesotenons, the annular ligament, or the flexor tendons themselves can result in lameness and a self-
perpetuating cycle of tendon sheath fibrosis, repeat tearing, and annular ligament thickening. Tenosynovial masses and adhesions can develop as a consequence of this chronic inflammatory action. These latter types of cases do not respond particularly well to medical therapy and not only require surgical intervention but also generally have a reduced prognosis for a cosmetic outcome and a return to complete soundness.

In animals in which the annular ligament causes constriction, chronic lameness (exacerbated by flexion of the fetlock), and tendon sheath effusion and thickening with a notching of the sheath over the width of the plantar annular ligament are common (Fig. 94-25). Ultrasonographic evaluation of the tendons within the canal is useful to determine the extent of tendon lesions and the thickness of the synovial tendon sheath and annular ligament and to define the number and attachments of tenosynovial masses. One report suggests that annular ligament desmitis can be the sole initiator of annular ligament constriction, and ultrasonographic evaluation is critical in making the diagnosis. Tears within the DDF tendon also are recognized as a cause of chronic severe tenosynovitis.

Treatment is commenced in chronic cases when a noticeable lameness has developed in conjunction with persistent swelling. Where tendon sheath masses and adhesions are evident on ultrasonographic examination or the annular ligament is thickened, surgical therapy is preferred for expeditious resolution of symptoms.

Mass Removal

Open tendon sheath approaches to mass and adhesion removal or resection have been successful. The disadvantage to extensive open approaches is the delay in the initiation of exercise postoperatively and adhesion formation or reformation. However, early postoperative walking increases the risk of wound dehiscence with the attendant risk of sepsis. For these reasons, endoscopic examination of the sheath (tenoscopy), using a standard rigid arthroscope, is preferred.

The entry portal for routine tenoscopy of the digital sheath is on the palmarolateral or plantarolateral surface immediately distal to the annular ligament. This entrance allows examination of most regions of the sheath, and instrument portals can be made proximal to the annular ligament under tenoscopic guidance. Tenosynovial masses can be resected either with motorized synovial resectors or by division at their attachments with biopsy cutting forceps or retractable blades and subsequent removal with grasping forceps (Fig. 94-26). For extensive synovial resection, hemorrhage control is required, and a tourniquet is applied proximal to the digital sheath. If annular ligament transaction also is needed, it can be accomplished initially to open further access for manipulation within the sheath, or at the end of the procedure, using the slotted cannula (Dyonics, Smith & Nephew, Memphis, Tenn) available for carpal tunnel release in humans.
Annular Ligament Transection

The only effective treatment for the annular ligament constriction syndrome is division of the ligament. Depending on the presence of tendon core lesions or peripheral adhesions, other surgical procedures such as tendon injection, mass removal, or adhesiolyis are performed as indicated. Preoperative planning is important for determining the degree of exposure of the tendons required to optimize treatment. Where only the annular ligament is involved, the ligament can be severed in the standing animal with a curved bistoury introduced through a 1-cm incision proximal to the ligament. However, in the majority of cases, other structures are involved, and general anesthesia and a larger incision provide access to evaluate and surgically treat these components.

In original descriptions of surgical division of the annular ligament, the skin was incised over the entire proximodistal length of the annular ligament. This incision provided access to allow sectioning of the annular ligament and subsequent division of adhesions under direct view. Where the annular ligament is the only involved structure, the exposure required for division of the ligament can be reduced to a 2-cm skin incision over the proximal border of the annular ligament. Another surgical approach involved a paramedian skin incision over the entire length of the annular ligament, followed by palmar or plantar transection of the ligament over the tenaculum (mesotenon). This technique, if performed correctly, prevented opening of the tendon sheath. It can be applied if only the annular ligament is involved.

Tenoscopic examination of the digital sheath with an arthroscope entering distal to the annular ligament allows visual inspection of the entire sheath cavity and division of the annular ligament (Fig. 94-27). Second entry portals allow adhesion resection and mass removal, as previously described, and with a slotted cannula (Dyonics, Smith & Nephew, Memphis, Tenn), endoscopic release of the annular ligament can be accomplished. The obvious advantages of tenoscopic annular ligament release include the extensive dissection that can be performed through limited entry wounds, allowing better wound healing with less risk of dehiscence and earlier postoperative exercise.

The entry and angle of the slotted cannula are critical to facilitate insertion of the arthroscope and 90-degree angled blade. The proximal entry portal should be dorsal in the digital sheath and the distal exit point should be plantar or palmar to allow the arthroscope or blades to clear the heel. The cannula with obturator in place is inserted under direct visualization from proximal to distal. The insertion path must be external to the manica flexoria, or this ring of the SDF will be divided along with the annular ligament. As the obturator nears the distal portal, the arthroscope is removed, and the obturator and cannula are exteriorized through the vacant portal.

The obturator is removed, and the unshathed arthroscope is inserted to view and verify the flexor tendons, sesamoid surface, and annular ligament. The slot is oriented to open directly toward the annular ligament, and the 90-degree-angle sharp blade is drawn across the fibers of the annular ligament to sever the full thickness of this structure. Arthroscopic guided free-hand division of the annular ligament using right-angled blades, radio-frequency probes, or bistoury can also be used. Hemorrhage is flushed from the cannula, which is then removed, and the tendon sheath is flushed before the skin incision is closed.

Tendon Débridement

Linear tears or clefts within the DDF tendon, and occasionally the SDF tendon, present special problems in repair, with most requiring débridement and some requiring suture. Ultrasonographic examination is not sensitive in detecting linear clefts in the tendon structure. Any ultrasonographic suggestion of echolucencies within the palmar or plantar third of the surface of the flexor tendons is highly suspicious, and this region should be carefully assessed.
during tenoscopic exploration. The linear clefts can penetrate a variable distance into the substance of the tendon. The treatment of choice is tenoscopic débridement (Fig. 94-28). Débridement has proved superior to suture repair following open surgical approaches.72 Tears in the DDF tendon can extend 4 to 10 cm. They often involve the DDF tendon from the level of the mid-proximal phalanx and extend beyond the level of the apex of the proximal sesamoid bones. The depth of the linear cleft varies from penetration to the center of the DDF tendon to more superficial fiber erosion. Trimming of exposed tendon fibers can be accomplished using a combination of biopsy punch rongeurs and motorized resectors with both side and forward aperture, which are also effective in trimming epitenal and tendon fiber damage. The aim should be a relatively smooth tendon surface. Hyaluronan (20 to 40 mg) is injected into the tendon sheath at the time of wound closure. Research in horses and experimental animals indicates hyaluronan reduces the formation and re-formation of tendon adhesions in the sheath area and enhances intrinsic tendon healing.73 The incidence of synovial fistulae associated with the extensive skin incision in the original description of annular ligament transection makes the smaller exposure and the use of tenoscopy attractive alternatives. Nevertheless, the maintenance of a firm bandage with careful changes and sterile nonadhesive padding is important. The limb is usually bandaged for 3 to 4 weeks after surgery. Although extensive tendon synovial mass and adhesion resection can be painful postoperatively, the majority of horses with simple annular ligament section do not require extensive analgesia. Stall confinement without exercise is recommended initially, but hand-walking should be instituted after 5 days and the time period should be increased rapidly. Long periods of walking exercise are particularly helpful if tendon adhesions were present at surgery. If adhesiolysis was performed at surgery, a follow-up injection of hyaluronan is recommended 2 weeks postoperatively.

Tenoscopic mass removal and annular ligament division in 25 horses followed for 6 to 68 months revealed cosmetically acceptable results in 22 of the horses. Lameness resolved in 18 of the 25 horses (72%). The poorest response was evident in two horses with concurrent tendinitis in the region of the digital sheath. The cosmetic outcome was inversely related to the preoperative duration of signs and the thickness of the annular ligament. In addition, a longer history of symptoms led to a thicker annular ligament on preoperative ultrasonography. Simple constrictive syndromes as a result of a wound, desmitis of the annular ligament, or chronic fibrosing synovitis of the tendon sheath have a good prognosis for return to work after sectioning of the annular ligament. The outlook is guarded where extensive tendon adhesions are resected, because these cases often have residual obliteration of the tendon sheath cavity with tendon tie-down in the proximal and distal limits of the sheath. Constriction caused by tendinitis of the flexors in the MCP canal is readily relieved by annular ligament division; however, return to work is governed by the poorly healing bowed tendon. A guarded prognosis is common, and extended periods of measured increases in activity are recommended. Follow-up ultrasonograms are useful to evaluate the repair of tendon lesions, particularly where core lesions were injected at the time of annular ligament transection.

Metacarpal and Metatarsal Bones

Dean W. Richardson

ANATOMY
The third metacarpal bone (MCIII) and third metatarsal (MTIII) bones are important and vulnerable elements of the forelimbs and hindlimbs, respectively. The small metacarpal and metatarsal bones (splay bones, MC or MT II and IV) are often termed vestigial, but both MCII and MTII have major weight-bearing functions, and MCIV and MTIV serve as sites for important carpal and tarsal ligamentous insertions. MCIII is slightly longer and typically more round in cross-section than MCIII. The cross-section of MCIII changes dramatically in response to increased loading as the horse ages and trains.

There is little soft tissue coverage of MCIII or MTIII except for their palmar or plantar aspects where the superficial and deep digital flexor tendons, accessory (check) ligament of the deep digital flexor, and the suspensory (interosseous) ligament are located. The suspensory ligament originates in a broad attachment on the proximal palmar or plantar aspect of the bones. The soft tissues in the proximal palmar or plantar aspects and trains.

In the forelimb, the major neurovascular structures course along the length of the metacarpus both medially and laterally just dorsal to the flexor tendons. In the hindlimb, the great metatarsal (dorsal III) artery’s location between the talo-crural and tarsal bones, respectively. The small metacarpal and metatarsal bones (splay bones, MC or MT II and IV) are often termed vestigial, but both MCII and MTII have major weight-bearing functions, and MCIV and MTIV serve as sites for important carpal and tarsal ligamentous insertions. MCIII is slightly longer and typically more round in cross-section than MCIII. The cross-section of MCIII changes dramatically in response to increased loading as the horse ages and trains.

Fractures of the metacarpus or metatarsus (MCIII or MTIII) are common long bone injuries of athletic horses. These are the most intensely loaded bones of the appendicular skeleton and are therefore vulnerable to single-event catastrophic failures as well as repetitive cyclic fatigue injuries. The most common site of major fracture of MCIII or MTIII is in the distal articulation. These bones are also common locations of kicking injuries in foals and adults, resulting in complete or incomplete fractures.

Condylar Fractures
Lateral Condylar Fractures
Vertical fractures in the sagittal plane occur in the distal condyle of MCIII or MTIII, predominantly in young racehorses, either during fast work or a race (Fig. 95-1). In Thoroughbreds, MCIII fractures are at least twice as common as MTIII fractures, but in Standardbreds, the ratio of forelimb to hindlimb fractures is more nearly equal.1-3}

Fractures in the right MCIII are significantly more likely to be displaced than those in the left.
CHAPTER 95

Metacarpal and Metatarsal Bones
Dean W. Richardson

ANATOMY

The third metacarpal bone (MCIII) and third metatarsal (MTIII) bones are important and vulnerable elements of the forelimbs and hindlimbs, respectively. The small metacarpal and metatarsal bones (splay bones, MC or MT II and IV) are often termed vestigial, but both MCII and MTII have major weight-bearing functions, and MCIV and MTIV serve as sites for important carpal and tarsal ligamentous insertions. MTIII is slightly longer and typically more round in cross-section than MCIII. The cross-section of MCIII changes dramatically in response to increased loading as the horse ages and trains.

There is little soft tissue coverage of MCIII or MTIII except for their palmar or plantar aspects where the superficial and deep digital flexor tendons, accessory (check) ligament of the deep digital flexor, and the suspensory (interosseous) ligament are located. The suspensory ligament originates in a broad attachment on the proximal palmar or plantar aspect of the bones. The soft tissues in the proximal palmar or plantar metacarpal and metatarsal regions also are invested in a retinacular sheath.

In the forelimb, the major neurovascular structures course along the length of the metacarpus both medially and laterally just dorsal to the flexor tendons. In the hindlimb, the great metatarsal (dorsal III) artery's location between the metatarsal (dorsal III) bones is in the distal articulation. These bones are also common long bone injuries of athletic horses. These are the most intensely loaded bones of the appendicular skeleton and are therefore vulnerable to single-event catastrophic failures as well as repetitive cyclic fatigue injuries. The most common site of major fracture of MCIII or MTIII is in the distal articulation. These bones are also common locations of kicking injuries in foals and adults, resulting in complete or incomplete fractures.

FRACTURES OF THE METACARPUS III AND METATARSUS III

Fractures of the metacarpus or metatarsus (MCIII or MTIII) are common long bone injuries of athletic horses. These are the most intensely loaded bones of the appendicular skeleton and are therefore vulnerable to single-event catastrophic failures as well as repetitive cyclic fatigue injuries. The most common site of major fracture of MCIII or MTIII is in the distal articulation. These bones are also common locations of kicking injuries in foals and adults, resulting in complete or incomplete fractures.

Condylar Fractures

Lateral Condylar Fractures

Vertical fractures in the sagittal plane occur in the distal condyle of MCIII or MTIII, predominantly in young racehorses, either during fast work or a race (Fig. 95-1). In Thoroughbreds, MCIII fractures are at least twice as common as MTIII fractures, but in Standardbreds, the ratio of forelimb to hindlimb fractures is more nearly equal.1-3 Fractures in the right MCIII are significantly more likely to be displaced than those in the left.

dorsoplantar (DP) projection or a radiograph in which the radiographs are obtained. An underexposed dorsopalmar or diaphysis.
propagate in a spiral plane or course centrally through the medial condylar fractures, lateral condylar fractures rarely exits 1 to 3 cm above the remnant of the physeal scar. Unlike the lateral cortex. Their height varies, but the typical fracture centimeters in a sagittal plane and proximolaterally toward mid to mid-axial portion of the lateral condyle for a few
more common.

Hindlimbs, lateral fractures are about three to four times more common than medial fractures, and in the lateral condyle.1-3 In the forelimbs, lateral fractures are seven times more common than medial fractures; however, the most typical presentation is an acute onset of severe lameness after intense exercise or a race. The fetlock almost always develops effusion, and there is overt pain on manipulation of this joint. The degree of lameness is not well correlated with the amount of fracture displacement; many horses with nondisplaced fractures are extremely lame, whereas some horses with large displaced fractures walk fairly well on the fractured limb.

Approximately 85% of all condylar fractures involve the lateral condyle.1-3 In the forelimbs, lateral fractures are seven times more common than medial fractures, and in the hindlimbs, lateral fractures are about three to four times more common

Nearly all lateral condylar fractures propagate from the mid to mid-axial portion of the lateral condyle for a few centimeters in a sagittal plane and proximolaterally toward the lateral cortex. Their height varies, but the typical fracture exits 1 to 3 cm above the remnant of the physeal scar. Unlike medial condylar fractures, lateral condylar fractures rarely propagate in a spiral plane or course centrally through the diaphysis.

Radiographic diagnosis is not difficult when good-quality radiographs are obtained. An underexposed dorsopalmar or dorsoplantar (DP) projection or a radiograph in which the distal margins of the proximal sesamoid bones are super-imposed over the metacarpophalangeal joint surface might not be diagnostic. This is avoided by taking the routine DP view in a slightly proximal-to-distal direction. Many horses have pre-existing degenerative disease involving the distal palmar or plantar condyle adjacent to the base of the ipsilateral proximal sesamoid bone, so an additional radiographic projection silhouetting this region is obtained by holding the fetlock in slight palmar flexion and taking a horizontal beam radiograph. This radiographic projection is used in all displaced condylar fractures because comminution along the fracture line is commonly identified in this location (Fig. 95-2). As imaging modalities such as computed tomography and magnetic resonance are used more, the repetitive stress injury in this location that predisposes to condylar fractures should be easier to recognize.

First aid for a lateral condylar fracture includes compression bandaging, nonsteroidal anti-inflammatory drugs, and absolute rest until definitive therapy is undertaken. The expense of cast coaptation is not justified because very few lateral condylar fractures will propagate if the horse is kept quiet in a heavy bandage. Manufactured splints and boots also are not indicated.

Clinical signs of lateral condylar fractures are typically straightforward, but incomplete fractures involving only the distal few centimeters of the condyle can present a diagnostic challenge. Horses might have a history of previous fetlock lameness preceding the onset of a more severe lameness; however, the most typical presentation is an acute onset of severe lameness after intense exercise or a race. The fetlock almost always develops effusion, and there is overt pain on manipulation of this joint. The degree of lameness is not well correlated with the amount of fracture displacement; many horses with nondisplaced fractures are extremely lame, whereas some horses with large displaced fractures walk fairly well on the fractured limb.

Nondisplaced fractures are repaired with screws applied in lag fashion. The screws prevent proximal propagation of the fracture and enhance articular healing, thus minimizing the potential for developing osteoarthritis. Surgical treatment is essential for displaced fractures because it provides anatomic reduction of the articular surface. Internal fixation renders the horse immediately more comfortable on the limb, thereby avoiding laminitis in the contralateral limb.

The disadvantages of surgery are those attendant on all general anesthetic procedures as well as the risk of infection and surgical error. However, condylar fractures can heal successfully without internal fixation, and a conservative approach is a reasonable consideration in nondisplaced fractures when there are economic limitations.

**Nondisplaced fractures**

Nondisplaced fractures are repaired with screws applied in lag fashion using minimum soft tissue dissection. The site of screw insertion is determined by topographic landmarks and intraoperative radiography or fluoroscopy. Radiopaque skin markers such as sterile skin staples can be used pre-operatively to select the sites for screw insertion. Alternatively, needles or other markers can be used intraoperatively.

The distal screw is placed as centrally as possible in the lateral condylar fossa. This site can be accurately estimated by taking the midpoint of an imaginary line drawn between the proximal palmar prominence of the proximal phalanx and the most dorsal aspect of the lateral condyle, both readily palpable landmarks. A stab incision is made to the surface of the bone in this location and parallel with the collateral ligament fibers to minimize injury to them. The surgeon can feel the scalpel slide into the fossa, confirming accurate placement of the incision.

Standard lag technique is used (see Chapter 81). The author prefers to drill the thread hole completely through the bone to avoid creating a blind hole. A blind hole can

**TREATMENT**

Surgical management of lateral condylar fractures involves compression of the fracture with cortex or shaft screws applied in lag fashion. The screws prevent proximal propagation of the fracture and enhance articular healing, thus minimizing the potential for developing osteoarthritis. Surgical treatment is essential for displaced fractures because it provides anatomic reduction of the articular surface. Internal fixation renders the horse immediately more comfortable on the limb, thereby avoiding laminitis in the contralateral limb.

The disadvantages of surgery are those attendant on all general anesthetic procedures as well as the risk of infection and surgical error. However, condylar fractures can heal successfully without internal fixation, and a conservative approach is a reasonable consideration in nondisplaced fractures when there are economic limitations.
cause the tap to break inadvertently or a too-long screw to be inserted, preventing solid compression of the fracture. As many additional screws as needed are placed at 15- to 20-mm intervals more proximally. Blindly placing a screw too close (less than 20 mm) to the proximal end of the fracture increases the risk of splitting the narrow end or entering a fracture line; a large majority of lateral condylar fractures can be treated with only two screws.

Correct positioning of the drill during the procedure is ensured through intraoperative radiographs (Fig. 95-3). Fluoroscopic image intensification is ideal, but plain films taken with small-diameter (2-mm) marker bits in place are
acceptable. With either, two perpendicular views should be taken to check positioning in the dorsopalmar and lateromedial planes.

Either 4.5- or 5.5-mm cortex screws can be used. It remains unclear whether the larger screws yield improved results, because screw failure is rarely a problem. The 4.5-mm screws have the advantage of being replaceable with a larger cortex screw if the bone threads are inadvertently stripped. In vitro, greater resistance of shaft screws to shear stress occurred compared with cortex screws, indicating that shaft screws are an option for repair of clinical cases.4

The majority of lateral condylar fractures can be treated with two screws. A few will propagate proximally enough to justify more screws, but usually the more proximal portion of the fragment is quite narrow in its dorsopalmar thickness, and accurate positioning of the screw in the center of that part of the fragment is difficult.

The most common technical errors in lag screw fixation of nondisplaced condylar fractures include inadequate compression and incorrect drill or screw placement. The former can be avoided by drilling the thread hole fully through the transcortex and being certain to completely tap that cortex. To minimize the chances of incorrect proximal to distal aiming of the drill, the MCIII or MTIII should be positioned parallel to the ground before draping. Most horses have some degree of external rotation of the limb (especially hindlimbs) when they are in lateral recumbency. The surgeon must account for this or the drill will be directed toward the palmar or plantar articular surfaces. Palpation of the medial and lateral wings of the proximal phalanx provides a good topographical key for the surgeon to direct the drill in a true lateral to medial direction.

Unless there is a strong economic reason not to do so, the dorsal and palmar or plantar joint should be examined arthroscopically to confirm fracture reduction and characterize pre-existing or fracture-associated cartilage damage.

Displaced fractures
Similar lag technique and positioning of the screws are used to treat a displaced fracture. Unlike nondisplaced fractures, displaced fractures demand accurate anatomic reduction and often exhibit more severe injury to the joint surfaces. There is little room for error in reducing a displaced fracture in an athletic horse.

Complete radiographic obliteration of the entire fracture line does not always occur, even with accurate reduction and screw placement and correct technique, because of fibrin lodged within the fracture plane or bone loss along its margins. However, if the articular surfaces are aligned, the horse has a good chance to heal with minimal arthritic change. If there is a step on the major weight-bearing surface of the condyle, osteoarthritis is likely to develop. A significant malalignment of the condyle also will produce very high bending and shear loads that can lead to bending or breaking of the screws.

The best technique for reduction of displaced lateral condylar fractures in most cases is by arthroscopic guidance (Fig. 95-4). To tentatively hold the reduction, the metacarpophalangeal (MCP) or metatarsophalangeal (MTP) joint is dorsiflexed, and a large pointed bone-reduction forceps is used through the intact skin at about the level of the physeal scar. After preparing a stab incision through the skin and collateral ligament, as previously described, the 4.5-mm glide hole is drilled through the fracture fragment using radiographic or fluoroscopic guidance. The glide hole should be drilled exactly to the fracture plane; this can be facilitated by temporarily removing the clamp so that it is possible to feel the drill enter the fracture plane. The insert
sleeve and a 3-mm pin are placed in the fragment to use as a handle.

The arthroscope is introduced into the proximal dorsolateral joint pouch. The MCP joint can be flexed, extended, or rotated and valgus or varus stresses can be applied until articular alignment is perfect. The pin inside the centering drill sleeve can be used for additional manipulation. When reduction is perfect, the reduction forceps are firmly reset and the remainder of the lag screw procedure performed.

The screw is inserted but not tightened. The arthroscope is repositioned and the articular compression and alignment are checked as the screw is firmly tightened. Subsequently, the palmar or plantar aspect of the joint is examined. Many comminuted fragments at the distal margin of MCIII or MTIII are immobilized by compression of the major fragment. If there are loose fragments, they can be removed under arthroscopic guidance. This is a difficult arthroscopic maneuver in some horses with chronic arthritis and capsular fibrosis. The instrument portal must be carefully positioned at the base of the lateral sesamoid, and instruments (curets, picks, and probes) with angled ends are invaluable.

Occasionally the fragment cannot be aligned properly because of interposed comminuted fragments. The pin and insert sleeve can be used to separate the dorsal aspect of the fracture plane to facilitate placement of the arthroscope and cannula into the fracture plane. A dorsal instrument portal exactly positioned over the fracture is made and the palmar fragments are retrieved.

If arthroscopic reduction is not feasible for some reason, enough of the fracture line should be exposed in displaced fractures to allow the surgeon to verify that reduction is accurate. In some cases this means a 2- to 3-cm incision over the proximal tip of the condylar fragment. In others, it means a longitudinal arthrotomy extending nearly to the proximal phalanx. In many horses, accurate reduction actually seems to get more difficult as the exposure is increased. It is always worthwhile to try to achieve accurate reduction using minimal exposure. It is imperative that postoperative radiographs are taken immediately to document correct surgical fixation of the fracture and create a comparative basis for follow-up radiographs.

Since arthroscopic examination of the entire joint has become a standard procedure, it has been recognized that sesamoid injury is often associated with condylar fractures. Most sesamoid damage involves varying degrees of erosion of articular cartilage, but more serious injuries also occur. Axial sesamoid fractures are often complications of displaced condylar fractures that should be identified preoperatively because they are associated with a very unfavorable prognosis. If an axial sesamoid fracture is present, repair of the condylar fracture should be done with the understanding that the horse has virtually no chance of returning to athletic competition. Axial sesamoid fractures are crescent shaped and represent an avulsion of the axial margin of the lateral proximal sesamoid bone by the intersesamoidean ligament (Fig. 95-5).

With large displaced fractures, the fragment can be fixed with one or two 3.5-mm cortex screws, but primary fetlock arthrodesis is probably a better option (see Chapter 85). In most axial fractures, a slender rim of articular surface is involved, but some fractures occur behind the articular surface and can be localized only with intraoperative radiographs or advanced imaging techniques such as computed tomography or magnetic resonance imaging.
Nearly all lateral condylar fractures can be successfully treated with screws alone. On occasion, however, lateral condylar fractures of the MCIII also have diaphyseal spiral or oblique components that demand they be treated with more extensive fixation as described for medial condylar fractures.

Medial Condylar Fractures

Medial condylar fractures are seen in both the forelimb and hindlimb of racehorses. Horses typically develop severe lameness immediately after exercise or become lame a few hours afterward. There is rarely significant soft-tissue swelling unless there is displacement of the fracture.

In most cases, the site of the lameness is readily identified by manipulation of the MCP joint, and dorsopalmar or plantar radiographs clearly reveal the medial condylar fracture. Preoperative radiographs of any medial condylar fracture should include a full series of projections over the entire length of the MCIII or MTIII.

Medial fractures are quite different in terms of configuration, treatment, and complications. They are not the mirror image of a lateral fracture. Medial fractures nearly always propagate toward the axial aspect of the MCIII or MTIII, either spiraling up the diaphysis or remaining nearly sagittal to the mid-diaphysis, where oblique fractures can later develop. Medial condylar fractures of MTIII are particularly prone to catastrophic failure when the horse stands following general anesthesia or even for several weeks after repair.

TREATMENT

Although internal fixation with multiple screws applied in lag fashion has been used successfully to treat many medial condylar fractures, plating techniques are preferable in most cases. Screws alone are not optimal for any fracture with a known oblique diaphyseal component; if an oblique or transverse diaphyseal fracture is identified in the preoperative radiographs, a plating technique should be used.

Approach

The plate and screws can be placed either medially or laterally. The fragments are equal enough in size and the bone is so dense that adequate fixation can be obtained with screws used in lag fashion, even if the threads are in the smaller fragment. The advantages of a dorsolateral approach are that the operated-on limb is uppermost and a lateral plate is easier to remove later under local anesthesia.

The incision is made in one layer down to the level of the bone surface. The periosteum is elevated, and the skin and underlying subcutaneous tissues are retracted together. When the surface of the cannon bone is exposed, the fracture line or lines are clearly defined (Fig. 95-6). The incision is continued distally to the level of the joint capsule, but the joint capsule is not incised.

A broad dynamic compression plate (DCP) is positioned extending from just above the second screw to the most...
proximal aspect of the bone. Typically, 10-hole or 12-hole plates are used for the MCIII and 12-hole or 14-hole plates are used for the MTIII. It is possible to spirally conform the plate if the specific configuration of the fracture is evident, but a straight plate can usually be safely applied in these nondisplaced fractures. Exposure of the diaphyseal bone surface allows accurate placement of additional screws across the fracture plane and centrally within the fracture fragment. Either 4.5-mm or 5.5-mm cortex or shaft screws are used (Fig. 95-7). Although anatomic placement of screws through the plate is straightforward, the suspensory ligament or splint bones, or both, can be inadvertently injured. Obliquely directed screws or dorsopalmarly directed screws are drilled with care to avoid penetrating these structures, especially if using the 4-mm drill bit needed for the thread hole with 5.5-mm screws.

Closure of the incision is routine if initially it was made in one plane. A simple interrupted cruciate pattern or simple continuous pattern of synthetic absorbable suture in the subcutis followed by routine skin closure is adequate. If special recovery systems are not available, a full-length hindlimb cast should be considered for metatarsal fractures. Half-limb casts should not be used for metatarsal fractures. Forelimb medial condylar fractures are usually re-covered in a full limb Robert Jones bandage.

An alternative technique is to place the bone plate using a minimally invasive technique. This is particularly applicable if there is no obvious proximal spiraling of the fracture. A 2-cm incision is made adjacent to the extensor tendon in the proximal MCIII or MTIII. A (previously used) broad DCP that has a sharpened end and is attached to a handle can be used to prepare a subcutaneous tunnel for the plate.

After the tunnel is prepared, a roughly contoured 10-hole or 12-hole broad 5.5-mm limited-contact dynamic compression plate (LC-DCP) (see Fig. 81-17) with tapered ends is slid into it. The fit of the plate is assessed by palpation and with fluoroscopy. The plate is recontoured as needed and replaced. The holes in the plate can be easily palpated. Stab incisions are made over the holes in either end of the plate and screws are inserted routinely. After inserting a screw through one proximal and one distal plate hole, a plate of the same length is placed on the surface of the skin and incisions are made through that plate’s holes. The remaining screws are inserted using routine technique. The distal few screws in the plate may be placed in lag fashion if the fracture plane is radiographically visible at that level. Fluoroscopy or intraoperative radiography is used to check implant positioning. One or two skin sutures are used for each stab incision.

Caution should be used with this technique to avoid piercing the contralateral splint bone with drill bits and screws. It is important to carefully check that each screw is fully inserted into the plate. It is particularly difficult to accurately measure the depth of holes, and therefore, intraoperative radiographic control is needed. Although it is possible to inadvertently place a screw in a fracture line, the overall stability the plate appears to be adequate to prevent catastrophic failure of the bone. All possible precautions should be taken during recovery from anesthesia, especially in metatarsal fractures.

Another option for the treatment of high-risk condylar fractures is to place screws (typically two) to repair the distal portion of the fracture with the horse under sedation and local anesthesia. Although this still carries a risk of catastrophic post-fixation failure, the highest risk of fracture is during recovery from general anesthesia.

**Aftercare**

Convalescence of horses with condylar fractures involves stall rest with strictly controlled exercise for at least 2 months. Some turnout in a small paddock is allowed in the third month, and the patients usually are returned to regular exercise in the fourth or fifth month. Displaced fractures or those with articular comminution are rested longer. The average time from surgery to first racing start is approximately 11 months.

Although there is no uniform agreement on the need to remove screws from condylar fractures, many horses have returned to racing with screws in place, and most horses do not have screws removed after repair of typical fractures. When fractures extend into the mid-diaphyseal region, the screws are more likely to cause pain when horses return to intensive exercise. Therefore, diaphyseal screws are removed 3 to 4 months after surgery, usually with the horse under sedation and local anesthesia. The limb is clipped and scrubbed for routine aseptic surgery, and sterile skin staples

---

Figure 95–7. Medial condylar fractures that do not spiral and appear to either disappear in the middiaphysis or turn sharply in an oblique path across the bone can be repaired with a bone plate.
are placed over the heads of the screws to be removed. Radiographs are taken to facilitate exact placement of the stab incisions over the screws if they cannot be clearly palpated. After the screws are removed, the horse is continued in a walking and jogging program for 60 to 90 days before returning to galloping exercise.

Plates used to treat medial condylar fractures are removed with the horse standing and under detomidine sedation and local anesthesia (see Chapters 20 and 74, respectively). These plates are typically removed about 70 to 80 days following surgery. Local anesthesia with direct infiltration over the implant or by means of a regional nerve block is performed, and a short incision is made over the proximal 2 cm of the plate (Fig. 95-8).

The most proximal screw is partially removed. A matching bone plate is placed on the skin, and stab incisions are made through its holes. Each screw is backed out above the skin edge but is not removed (Fig. 95-9). After the screws are all counted, they are removed. This helps prevent looking for a screw that has already been removed as well as preventing trying to remove a plate that still is secured with a screw. A battery-powered drill with the screwdriver attachment is quieter and easier to use in a standing horse.

A 12-mm osteotome is used to pry the plate up at its proximal end. The osteotome is left under the end of the plate, and the plate is grasped with sterile vise grips and extracted proximally. A single skin suture per screw is placed, and the larger proximal incision is closed in two layers.

The horse should be hand-walked for 60 days. It can be turned out into the paddock for another month and then gradually return to training.

**Prognosis**

Prognosis for condylar fractures is favorable (70% to 80% return to full function) if there is minimal pre-existing osteoarthritis and the fracture is not displaced. Displacement requiring open reduction of the fracture lessens the prognosis considerably, both because of the surgical trauma and because there typically is more injury to the joint surfaces (comminution, degenerative changes, sesamoid injury).

The prognosis for displaced lateral condylar fractures of MCIII is about 50% for return to racing, less if there is serious comminution or sesamoid injury. Lateral condylar fractures of MTIII have a better prognosis than those of MCIII.
The prognosis for medial fractures is more variable and depends on the development of catastrophic complications. Complications of medial condylar fractures can occur before surgery, during recovery, or even weeks afterward. Therefore, by far the most important aspect of managing medial condylar fractures is to appropriately advise the owner of complications that can occur.

Diaphyseal Fractures
The most common major long bone fracture in horses is MCIII or MTIII, and diaphyseal fractures are the most often encountered. They occur in any age animal and during any type of activity. Many occur as pasture accidents.

There are favorable and unfavorable aspects to repairing fractures of MCIII or MTIII. Factors favoring successful repair are access and exposure of the entire diaphysis, making reduction and internal fixation feasible; strong bone to which screws and plates can be affixed; and the possibility of immobilization by external coaptation. Factors that do not favor repair are quite significant and include minimal soft-tissue coverage, which often leads to open fractures; no muscles adjacent to the fracture, resulting in poor extraosseous blood supply to the fracture site; sparse vascularity of the distal limb; and comminution, especially in older horses.

The diagnosis of diaphyseal MCIII or MTIII fractures is straightforward. In a frantic horse, radiography should be delayed until first aid has been administered and a preliminary decision has been made concerning treatment. It is particularly important not to risk opening a closed fracture by extended attempts to obtain radiographs. First aid for MCIII or MTIII fractures must include appropriate external coaptation (see Chapter 78).

Nonsurgical Management
Cast or splint coaptation as the sole treatment of displaced diaphyseal MCIII or MTIII fractures is rarely an acceptable approach. These fractures are unstable. Horses almost never become comfortable with simple external coaptation, and problems in the contralateral limb develop quickly.

Furthermore, the lack of soft-tissue coverage over unstable MCIII or MTIII fractures can allow the fractures to open, even in a well-fitted cast.

In young animals, even though fracture healing occurs more quickly, cast coaptation is not the treatment of choice because permanent deformities develop rapidly in the contralateral limb and serious flexor or suspensory weakness occurs in the cast limb. Even if the fracture heals when treated in this manner, the problems associated with cast immobilization usually result in a less-than-optimal outcome.

Surgical Management
Internal fixation is the treatment of choice for diaphyseal cannon bone fractures. Although external skeletal fixation and intramedullary interlocking nails have been used, the optimal treatment remains double-plate fixation. Double-plating is usually necessary in foals and is always indicated in larger horses.

A dorsolateral surgical approach is used, splitting the digital extensor tendons. The skin incision is carried directly to the underlying bone through the periosteum (Fig. 95-10, A). The periosteum is elevated to allow reduction and reconstruction. Unlike in heavily muscled parts of the limb, reduction of MCIII or MTIII fractures is not usually difficult.

Reduction of simple fractures is maintained with large pointed reduction forceps or by inserting strategically placed compression screws. The sites for screw insertion are selected after planning plate application. If the only practical sites for the screws will be under a plate, 3.5-mm screws that are deeply countersunk are placed to hold the reduction while the plates are applied.

After reduction is secure with clamps, lag screws, or both, an aluminum template is used to help shape the two plates. The plates are placed dorsolaterally and dorsomedially at 90 degrees relative to each other unless fracture configuration dictates otherwise. In a large adult horse, two broad plates with 5.5-mm screws are used, but in a foal, one broad and one narrow plate are adequate. The plates are staggered so that screws placed perpendicularly through one plate will...
not interfere with those from the other. All screw holes in the plates should be used; even if a hole is directly over a fracture line, a screw can nearly always be inserted that will engage at least one cortex. Both plates should be as long as possible without involving the joints or physis (see Fig. 95-10, B). Plate luting is recommended in larger horses with unstable fractures. The newer technology of locking compression plates (LCPs; see Chapter 81) should also be strongly considered if the additional expense of these implants can be justified.

An autologous cancellous bone graft should always be used if there are any cortical defects (see Chapter 82). It is best to perform the surgery as soon as possible after the injury because eburnation of the fragment ends makes reduction difficult and the repaired fracture less stable.

The incision is closed by initially apposing the tendon edges with interrupted synthetic absorbable sutures. Subcuticular and skin closure are routine.

The decision to use a cast versus a bandage on the limb depends on the horse’s age, size, postoperative care, apparent stability of the repair, and available special recovery systems. A cast is used to protect the repair during recovery from anesthesia, but long-term protection of the repair with a cast is often undesirable because of the inevitable flexor weakness that develops. In general, foals younger than 1 year of age are not cast except for recovery. Casts are used in adult horses when the fixation is considered less than secure.

The major complication of MCIII or MTIII fractures is infection because of the relatively poor vascularity of the region, poor soft-tissue coverage, a large metal-to-bone ratio, and the commonness of open injury. Implant failure (loosening or breakage) is possible but less of a concern if correctly sized and positioned implants are used.

Distal Physeal Fractures
Distal physeal fractures of MCIII or MTIII are common injuries in suckling and weanling foals. Nearly all are Salter-Harris type II fractures with a variable length of metaphyseal involvement (Fig. 95-11, A). Such injuries usually heal relatively quickly with minimal surgical management. Young foals (younger than 6 weeks old) with these fractures can be treated with cast coaptation alone for 2 to 3 weeks followed by 2 to 3 additional weeks in a splinted bandage. If the fracture appears reasonably stable and the foal is comfortable, even less coaptation could be adequate.

In older, heavier foals or those with marked instability, the fracture can be repaired with compression screws through the metaphyseal component in addition to external coaptation (see Fig. 95-11, B). Although such minimal internal fixation is not inherently stable, it is adequate if combined with external coaptation in young foals because physeal injuries heal quite rapidly. It is preferable not to span this growth plate with any implants in animals intended for athletic function.

Regardless of the technique used to treat the fracture, the foal’s return to exercise is carefully graduated over several weeks while the ligamentous and musculotendinous tissues regain strength.

Proximal Articular Fractures
Proximal articular fractures of MCIII or MTIII occur sporadically in racehorses and can be confusing because the lameness associated with them is typically eliminated by local anesthetic injected into the middle carpal or tarso-metatarsal joint.

Sagittal fractures can be seen in any breed; most occur medial to the midline and are best diagnosed by nuclear scintigraphy and excellent-quality dorsopalmar or plantar radiographs. Occasionally, the fracture can be identified ultrasonographically as linear discontinuity in the proximal palmar or plantar cortex. Frontal plane fractures occur in MCIII or MTIII (Fig. 95-12, A). In Standardbreds, the fracture is most common in young pacers on the dorsomedial aspect of MCIII.

All proximal articular fractures have been treated conservatively with good success, but displaced frontal plane fractures are best repaired with internal fixation using compression screws (see Fig. 95-12, B). The sagittal plane
Fractures are rarely displaced and will heal with stall rest alone.

**Dorsal Cortical Fractures**

A large percentage of young Thoroughbred horses in race training develop pain and lameness associated with the dorsal cortex of MCIII; this is called *bucked shins*. In the majority of horses, no specific fracture line is identified, but some develop one or more oblique radiolucent lines in the dorsal cortex accompanied by focal pain and swelling. These so-called stress fractures occur most commonly in 3-year-old Thoroughbreds after they experience bucked shin problems in their 2-year-old season.

The most common configuration of such fractures is a line coursing proximally at a 30- to 40-degree angle from the surface of the mid-distal dorsolateral cortex of the left MCIII (Fig. 95-13). Typically, the fissure extends approximately 60% to 70% through the dorsal cortex and disappears, but in some cases, the crack curves proximally and courses back to the dorsal cortex, forming a true saucer fracture. Fractures can occur in the opposite configuration (proximodorsal to distopalmar) as well as anywhere along the length of MCIII.

**Nonsurgical Management**

Treatment of dorsal cortical fractures can be conservative, with anti-inflammatory agents and rest (stall and paddock) until the fracture is radiographically healed. Some trainers return the horse to a diminished exercise program as soon as the overt lameness abates and then simply follow the progress of healing with sequential radiographs.

Many horses heal without surgical intervention, but a significant percentage have no signs of radiographic healing.

**Figure 95-12.** A, Radiographic view of a nondisplaced proximal articular fracture of the third metacarpus (MCIII). B, The fracture was repaired with three 5.5-mm cortex screws placed in lag fashion. Note the distal-most screw was not completely inserted, even though the hole was drilled completely across the bone. The fracture went on to heal because solid interfragmentary compression was achieved with the proximal two screws. (Courtesy J. Auer, University of Zurich.)

**Figure 95-13.** Xeroradiograph of a typical dorsal cortical stress fracture of the third metacarpus (MCIII) in a 3-year-old Thoroughbred racehorse. Optimal-quality films are always desirable to diagnose such injuries.
even after several months. The best candidates for conservative treatment are fractures in the distal or proximal metaphyseal regions of MCIII because they develop periosteal bridging callus much more rapidly than the typical intracortical fracture in the diaphysis.

Extracorporeal shock wave therapy has also been extensively used in the management of bucked shins and dorsal cortical fractures. There is controversy about its efficacy and whether or not a major effect of the shock wave treatment is primary analgesia.

Surgical Management

Surgical treatment of dorsal cortical fractures of MCIII is osteostixis alone or in combination with an intracortically placed 3.5-mm cortex screw. The advantage of osteostixis alone is that it avoids a second operation to remove the screw. More-consistent results have been achieved with the combination treatment followed by routine screw removal at 60 days.

The surgery can be carried out under either general anesthesia or sedation and local anesthesia. Local anesthesia has the obvious advantage of avoiding the risks of general anesthesia and recovery, but it has the possible disadvantage of unexpected movement during drilling, leading to broken drill bits and taps.

It is important to accurately locate the exact site of the fracture preoperatively because it can often be very difficult to visually identify it at surgery. A useful technique is to take a radiograph of the limb after surgically preparing the skin and place multiple skin staples in a grid over the affected region, varying the orientation of the staples so that they can be easily identified (Fig. 95-14). This allows precise positioning of the incision over the fracture.

A 4- to 6-cm incision is made over the fracture site. In the typical dorsolateral fracture, the incision is between the common digital and lateral digital extensor tendons. The incision is made boldly directly to the level of the perios- teum to minimize dissection. The periosteum is elevated, and self-retaining retractors are placed to expose the bone surface.

If a lag technique is used, the 3.5-mm glide hole is placed as perpendicular as possible to the middle of the radiographically identifiable fracture line. The depth of the glide hole is determined by measuring the actual depth of the hole and comparing it with the distance read off the radiograph. It is impossible to feel the drill cross the fracture line. Measuring the glide hole as it is drilled can result in error because the distance to the fracture line varies considerably with minor changes in the expected entrance point and obliquity of the drill path. Alternatively, because compression of the fracture is not necessary for successful treatment, a position screw (without a glide hole) within the dorsal cortex is often placed.

A small bit is used to drill across the dorsal MCIII, with irrigation and frequent cleaning of the bit to avoid breaking the bit or causing thermal injury. Because the screw is inserted at an acute angle, countersinking is necessary to prevent the screw from bending at the head as it is tightened. The amount of countersinking should be minimal, however, because excessive depth of the head makes screw removal much more difficult. Most dorsal cortices accommodate a 22-mm screw. Because of the bending that occurs in the mid-diaphysis of the MCIII, a screw across both cortices is not recommended.

After the screw is implanted, six or seven osteostixis holes are drilled with a 3.2-mm or 2-mm drill bit across the dorsal cortex. The holes are drilled at a distance of approximately 20 mm between them all around the fracture (Fig. 95-15). Closure and bandaging of the area are routine.

Postoperative care includes stall rest and hand-walking for 2 to 4 weeks followed by 4 to 6 weeks of stall rest and paddock exercise. At 60 days postoperatively, the horse is returned for screw removal, which is easily performed in the standing animal under sedation and local anesthesia.

If the screw head cannot be palpated, a grid of sterile skin staples can be placed over the area and a radiograph taken to locate the ideal site for a small incision. Local infiltration at the site of the screw head is adequate. Because the hexagonal recess of the 3.5-mm screw head is quite shallow, it is easily stripped; therefore, the screw head recess should be completely cleaned with a needle, sharp hook, or small pin before inserting the screwdriver tip to prevent this complication. If it does strip, the head is grasped with locking pliers and removed.
After the screw is removed, the horse is hand-walked for another month. The horse can begin a jogging program for about 6 to 8 weeks before returning to regular race training.

FRACTURES OF THE SMALL METACARPAL OR METATARSAL BONES

Fractures of the small metacarpal or metatarsal bones occur during exercise or as a result of direct trauma, such as kicks. The former are closed injuries, and the latter are often open. Clinical diagnosis is straightforward because pain and swelling are palpable and radiographs are simple to obtain and interpret. Ultrasonography is performed to assess concurrent injury to the suspensory ligament.

Distal Fractures

Distal splint bone fractures (those involving the distal half of the bone) are treated by surgical excision of the distal fragment (Fig. 95-16, A). The surgery is technically simple and can be successfully performed under general anesthesia or with the horse standing under local anesthesia.

Although this surgery can be carried out with an Esmarch bandage or tourniquet, bleeding is usually modest and rarely slows the procedure. In cases with extensive contamination, an Esmarch bandage can allow much more accurate debridement because foreign material is more easily recognized.

An incision is made directly over the bone, cutting down to the bone surface over the length of the fragment. The distal tip of the fragment is grasped with towel clamps or tissue forceps and elevated. The attachments between the distal fragment and MCIII are severed with heavy curved scissors or a 6-mm osteotome. As upward traction is applied on the fragment’s extremity, sharp dissection is continued proximally to approximately 8 to 16 mm proximal to the fracture site.

After the distal fragment and the fracture callus are separated from MCIII or MTIII, the splint bone with its periosteum is transected obliquely in a proximal abaxial to distal axial direction with an osteotome and mallet. The distal stump and the bed of the removed fragment are checked for loose fragments or jagged edges (see Fig. 95-16, B). If found, these are removed with rongeurs or a curet. The wound is checked for bleeding vessels, which are cauterized or ligated.

The incision is closed in routine fashion in two layers, and an adhesive elastic pressure bandage is applied over a light sterile dressing. This is in turn covered with a padded bandage to further minimize bleeding into the dead space.

Prognosis depends to a great extent on the coexistence and degree of suspensory desmitis, sesamoiditis, or MCP joint disease. Thus it is essential to preoperatively evaluate adjacent tissues with physical examination, radiographs, and ultrasonography.

Prognosis after larger distal fragments of splint bones are removed depends on the size of the fragment removed as well as the specific bone involved. The entire MTIV can be
removed with good results, but removal of more than 50% of MCII can lead to carpometacarpal instability and lameness because MCII bears a substantial axial load. Therefore, an effort should be made to repair rather than remove fractures of the proximal half of MCII.

**Proximal Fractures**

Internal fixation of splint fractures is indicated for fractures involving the proximal half of MCII and the proximal third of MCIV, MTII, or MTIV. Although large fragments have been removed and the remaining portion successfully fixed to MCIII or MTIII, motion between the bones commonly leads to lameness. Plate fixation in which the screws engage only the splint bone is the preferred technique for simple displaced fractures of the proximal splint bone. Comminuted fractures are treated conservatively because many heal adequately with bandaging and stall rest.

A slightly curved incision is made long enough so the plate is not positioned directly under it. A 3.5-mm narrow dynamic compression plate, a 3.5-mm semitubular plate, or a 3.5-mm reconstruction plate is used, even in a large horse. Principles of plate application do not differ from those of other fractures (see Chapter 81).

The ligamentous attachments on the abaxial surfaces of the proximal splints make the palmar or plantar abaxial aspect a tension surface, and the plate is best positioned there. Most fractures are oblique; thus the best technique is neutralization plating with screws applied in lag fashion across the fracture line (through the plate) (Fig. 95-17). A cancellous graft is placed in large defects, although the surgeon should be careful not to place it axially so that the suspensory ligament becomes entrapped in new bone. In open fractures, antibiotic-impregnated polymethylmethacrylate (PMMA) beads may also be placed at the fracture site.

Cast coaptation is not necessary postoperatively. If the fracture cannot be successfully plated without engaging the cannon bone, the plate will need to be removed about 3 to 4 months after surgery, before the horse goes back into strenuous work.

The plate can be removed through stab incisions. One screw in the plate is identified and removed. A matching plate is placed over the site, allowing accurate estimation of the other screw positions. Small stab incisions are made to remove the screws. A skin stab at the end of the plate is enlarged slightly, allowing the plate to be grasped with vise grips or a similar instrument and slid out of the incision.

The prognosis for most splint fractures repaired with plate fixation is excellent. The major complication is sepsis, particularly if the original injury was caused by external trauma. Fortunately, the limited weightbearing of the splint bone allows successful management when there is contamination and sepsis.

![Figure 95-17. A, Most proximal fractures of MCII are oblique and involve the articular surface. B, A 3.5-mm reconstruction plate was applied. Screws alone are vulnerable to pull-out because of the collateral ligament attachment.](image)
Splint Exostoses

Most horses with exostoses involving the splint bone are not candidates for surgery except for cosmetic purposes. If cosmetic removal of a splint is undertaken, it is essential to inform the owner that the site might not have a blemish-free appearance. This is particularly true of splint exostoses that develop because of overt conformational abnormalities such as bench knees or carpus varus deformities.

Although there is no surgical technique that consistently produces elimination of a blemish, the best technique is a simple linear incision over the exostosis and en bloc excision of the entire bone mass. This excision should include the overlying periosteum. An oscillating saw or a sharp-bladed osteotome is used to cut the excessive bone and return it to a normal contour. Often, separation of the proliferative bone from normal bone occurs without effort once the level is identified. Transection of the metacarpal nerve coursing axially to the affected portion of the splint has been proposed to eliminate lameness.

Axial exostoses are the cause of lameness because of impingement on the suspensory ligament. The presence of such an exostosis (hidden splint) is diagnosed with dorsopalmar radiographs. The problem is verified with computed tomography. In diagnosed cases, surgical removal of the splint can be attempted with the same restrictions discussed above. The lesion is approached through a skin incision over the palmar or plantar aspect of the splint bone involved. The axial fascia is transected, and the suspensory ligament is carefully displaced. Removal of the exostosis is routine. Care is taken to avoid damage to the suspensory ligament.

Good hemostasis is verified, the loose subcutaneous tissues are closed over the exposed bone surface, and the skin edges are apposed routinely. In very large exostoses, a portion of the skin margin is excised to reduce the tendency for hematoma or seroma to develop.

The most critical aspect of managing cosmetic splint removals is postoperative bandaging. A tight internal bandage applying direct pressure over the surgery site followed by an outer padded compression bandage should be kept in place for several weeks to minimize the accumulation of blood or serum at the surgical site.

POLYDACTYLY

Polydactyly of the metacarpal or metatarsal region occurs occasionally as a congenital defect (Fig. 95-18). The milder forms that do not compromise the carpus or tarsus too extensively can be successfully managed by surgical excision of the extra metacarpus and digit.

based on return to racing soundness. The expected outcome after injury and treatment is
Carpal injuries in the horse occur most often in racing breeds. The expected outcome after injury and treatment is based on return to racing soundness.

ANATOMY
The carpus consists of three joints: antebrachiocarpal, middle carpal, and carpometacarpal. The middle carpal and carpometacarpal joints always communicate with each other. This fact is important when considering intra-articular and regional anesthesia of the proximal palmar metacarpus.

Injury of the carpometacarpal joint is mostly desensitized by intra-articular anesthesia of the middle carpal joint. Likewise, middle carpal joint injury can be desensitized if an anesthetic agent is inadvertently placed in the palmar aspect of the carpometacarpal joint during regional anesthesia of the proximal palmar metacarpus. Studies have indicated that analgesia of the antebrachiocarpal and middle joints is not specific either. In one study, diffusion of mepivacaine that analgesia of the antebrachiocarpal and middle joints is not specific either. In one study, diffusion of mepivacaine between the antebrachiocarpal and middle carpal joints occurred in 96% of the tested limbs, and diffusion between the antebrachiocarpal and middle carpal joints occurred in 84% of the tested limbs, and diffusion between the middle and antebrachiocarpal joints occurred in 96% of tested limbs. Therefore, a positive response to intraarticular anesthesia of one portion of the carpus might not specifically implicate that joint as the source of lameness. This information confirms clinical experiences in horses that block out variably in the carpal and proximal metacarpal region.

The bones that compose the carpus include the radius; the proximal row of carpal bones (radial carpal, intermediate carpal, and ulnar carpal); the distal row of carpal bones (second, third, and fourth carpal); the metacarpal (MC) bones II, III, and IV; the accessory carpal bone; and occasionally a first carpal bone (but rarely a fifth). The orientation of the carpal bones relative to themselves is maintained by their soft-tissue attachments, including the intercarpal ligaments, collateral ligaments, fibrous joint capsule, and palmar carpal ligament. The extensor carpi radialis and common digital extensor tendons as well as their sheaths span the carpus dorsally and dorsolaterally, respectively. They are maintained in their position over the dorsal surface of the carpus by the extensor retinaculum located at the proximal radius approximately at the level of the physeseal scar. The lateral digital extensor tendon courses over the lateral side of the carpus, as does the tendon of the ulnaris lateralis. Palmar and medial to the palmar carpal ligament is the carpal canal, a synovial structure in which the superficial and deep digital flexor tendons, median artery, and nerve are located. Immediately medial to the carpal canal is the tendon and tendon sheath of the flexor carpi radialis, which is an important surgical landmark for desmotomy of the proximal check ligament.

The function of the bony and ligamentous structures of the carpus is to dissipate axial loading during weight-bearing. The anatomic position of the carpal bones and the resultant transmission of forces to the intercarpal ligaments protect the weight-bearing surfaces of the carpal bones during exercise to prevent injury. Loss of interosseous fibrous connections promotes instability, lameness, and osteoarthritis. The support of the cuboidal bones and the compressive stiffness of the hyaline cartilage are key to carpal function.

PATHOPHYSIOLOGY
Injury to the carpus most commonly occurs within the antebrachiocarpal and middle carpal joints. Injury of the proximal metacarpus, which can involve the carpometacarpal joint, is discussed in Chapter 95. Osteochondral fragments occur in both the dorsolateral and dorsomedial aspect of the antebrachiocarpal joint. Injury of the middle carpal joint nearly always involves the medial aspect of the joint—that is, the radial facet of the third carpal bone, the distal aspect of the radial carpal bone, and occasionally the medial aspect of the distal intermediate carpal bone.

High-energy injuries such as falls or kicks to the carpus cause acute single load failure. The resultant injury often causes open or comminuted fractures and carpal instability. (For additional details on stabilizing luxations of the carpus, see Chapter 85.) These injuries, however, are less common than those developing as a result of repetitive loading. During training, axial loading of the carpus occurs and stress-adaptive remodeling of the carpal bones is induced. Alterations in bone porosity and stiffness can predispose the bone to fracture.
9. Dallap B, Bramlage LR, Emberson RM: Results of screw fixation of the carpometacarpal joint during regional anesthesia of the proximal palmar metacarpus.1 Studies have indicated that analgesia of the antebrachiocarpal and middle joints is not specific either. In one study, diffusion of mepivacaine that analgesia of the antebrachiocarpal and middle joints is maintained by their soft-tissue attachments, including the intercarpal ligaments, collateral ligaments, fibrous joint capsule, and palmar carpal ligament. The extensor carpi radialis and common digital extensor tendons as well as their sheaths span the carpus dorsally and dorsolaterally, respectively. They are maintained in their position over the dorsal surface of the carpus by the extensor retinaculum located at the distal radius approximately at the level of the physesal. The lateral digital extensor tendon courses over the lateral side of the carpus, as does the tendon of the ulnaris lateralis. Palmar and medial to the palmar carpal ligament is the carpal canal, a synovial structure in which the superficial and deep digital flexor tendons, median artery, and nerve are located. Immediately medial to the carpal canal is the tendon and tendon sheath of the flexor carpi radialis, which is an important surgical landmark for desmotomy of the proximal check ligament.

CHAPTER 96

Carpus

Alan J. Ruggles

Carpal injuries in the horse occur most often in racing breeds. The expected outcome after injury and treatment is based on return to racing soundness.

ANATOMY

The carpus consists of three joints: antebrachiocarpal, middle carpal, and carpometacarpal. The middle carpal and carpometacarpal joints always communicate with each other. This fact is important when considering intra-articular and regional anesthesia of the proximal palmar metacarpus. Injury of the carpometacarpal joint is mostly desensitized by intra-articular anesthesia of the middle carpal joint. Likewise, middle carpal joint injury can be desensitized if an anesthetic agent is inadvertently placed in the palmar aspect of the carpometacarpal joint during regional anesthesia of the proximal palmar metacarpus. Studies have indicated that analgesia of the antebrachiocarpal and middle joints is not specific either. In one study, diffusion of mepivacaine between the antebrachiocarpal and middle carpal joints occurred in 84% of the tested limbs, and diffusion between the middle and antebrachiocarpal joints occurred in 96% of tested limbs. Therefore, a positive response to intrasynovial anesthesia of one portion of the carpus might not specifically implicate that joint as the source of lameness. This information confirms clinical experiences in horses that block out variably in the carpal and proximal metacarpal region.

The bones that compose the carpus include the radius; the proximal row of carpal bones (radial carpal, intermediate carpal, and ulnar carpal); the distal row of carpal bones (second, third, and fourth carpal); the metacarpal (MC) bones II, III, and IV; the accessory carpal bone; and occasionally a first carpal bone (but rarely a fifth). The orientation of the carpal bones relative to themselves is maintained by their soft-tissue attachments, including the intercarpal ligaments, collateral ligaments, fibrous joint capsule, and palmar carpal ligament. The extensor carpi radialis and common digital extensor tendons as well as their sheaths span the carpus dorsally and dorsolaterally, respectively. They are maintained in their position over the dorsal surface of the carpus by the extensor retinaculum located at the distal radius approximately at the level of the physesal. The lateral digital extensor tendon courses over the lateral side of the carpus, as does the tendon of the ulnaris lateralis. Palmar and medial to the palmar carpal ligament is the carpal canal, a synovial structure in which the superficial and deep digital flexor tendons, median artery, and nerve are located. Immediately medial to the carpal canal is the tendon and tendon sheath of the flexor carpi radialis, which is an important surgical landmark for desmotomy of the proximal check ligament.

The function of the bony and ligamentous structures of the carpus is to dissipate axial loading during weight-bearing. The anatomic position of the carpal bones and the resultant transmission of forces to the intercarpal ligaments protect the weight-bearing surfaces of the carpal bones during exercise to prevent injury. Loss of interosseous fibrous connections promotes instability, lameness, and osteoarthritis. The support of the cuboidal bones and the compressive stiffness of the hyaline cartilage are key to carpal function.

PATHOPHYSIOLOGY

Injury to the carpus most commonly occurs within the antebrachiocarpal and middle carpal joints. Injury of the proximal metacarpus, which can involve the carpometacarpal joint, is discussed in Chapter 95. Osteochondral fragments occur in both the dorsolateral and dorsomedial aspect of the antebrachiocarpal joint. Injury of the middle carpal joint nearly always involves the medial aspect of the joint—that is, the radial facet of the third carpal bone, the distal aspect of the radial carpal bone, and occasionally the medial aspect of the distal intermediate carpal bone. High-energy injuries such as falls or kicks to the carpus cause acute single load failure. The resultant injury often causes open or comminuted fractures and carpal instability. (For additional details on stabilizing luxations of the carpus, see Chapter 85.) These injuries, however, are less common than those developing as a result of repetitive loading. During training, axial loading of the carpus occurs and stress-adaptive remodeling of the carpal bones is induced. Alterations in bone porosity and stiffness can predispose the bone to fracture.
Exercise induces regional changes in bone density, which can be associated with the characteristic location of carpal injury. In one study, Thoroughbred horses exercised on a treadmill had increased trabecular thickening and increased bone mineral density in the third and radial carpal bones, in areas where cartilage degeneration and fractures occur commonly. Previous work had identified increased areas of bone stiffness in the radial facet of the third carpal bone. Loss of compressive stiffness of the subchondral bone plate subsequent to exercise, which is manifested by sclerosis on a radiograph, likely contributes to fractures of the carpus.

Likewise, cartilage injury has been correlated with underlying bone sclerosis. Training has been shown to increase the thickness of the zone of calcified cartilage. The effect of this thickening is unknown, but it might be protective by maintaining the stiffness gradient between hyaline cartilage and subchondral bone of increased stiffness. Conversely, the relative increase in calcified to hyaline cartilage and resultant tidemark advancement could represent a pathologic process and predispose these areas of bone to failure.

The result of repetitive loading of the carpal bones is stress-adaptive remodeling. In some horses, the loss of compressive stiffness of the subchondral bone plate and thickening of the calcified layer of cartilage can lead to cartilage injury and fracture.

Injury to the intercarpal ligaments can occur and usually involves the palmar medial intercarpal ligament within the middle carpal joint. Injury to the collateral ligaments is usually associated with avulsion fractures of the proximal aspect of the small metacarpal bones or distal radius. Injury to the extensor tendons usually develops in association with severe flexural deformities or lacerations. Injuries to the palmar aspect of the carpus occur, but they are less common than dorsal injury and have been associated with hyperextension of the carpus during recovery from anesthesia.

The role of conformation and carpal injury is complex and subject to personal opinion and anecdotal information. It is an area of intense concern in prepurchase examinations. One study found an association between offset carpi and lameness associated with the metacarpophalangeal joint and a protective effect of carpal valgus on carpal injury. These observations are consistent with the author’s clinical experience. Severe conformational abnormalities of foals can lead to malformation of the cuboidal bones and early osteoarthritis.

**OSTEOCHONDRAL FRAGMENTS**

**Occurrence**

Osteochondral fractures of the carpal bones, or carpal chips, are a common cause of lameness in horses. Racing breeds are particularly prone to carpal chip fractures, and the fractures are most likely to be a performance-limiting problem.

The occurrence of osteochondral fragmentation is a consequence of training and racing. In support of this, in Thoroughbred yearlings radiographed prior to sale, only 9 of 1121 horses (0.8%) had an osteochondral fragment in the carpus. In racing Thoroughbreds and Quarter Horses, the distal aspect of the radial carpal bone is most often affected. In another survey of osteochondral fragmentation in racing Thoroughbreds in Japan, 60% of the fractures occur in the antebrachiocarpal joint and 40% in the middle carpal joint.

Additional articular damage associated with osteochondral fragments tended to be greatest in the middle carpal joint. If the injury involves the antebrachiocarpal joint, the distal lateral aspects of the radius and the proximal intermediate carpal bone are usually involved. If the middle carpal joint is involved, then the distal radial carpal and proximal third carpal bones are typically involved.

Racing Standardbreds typically injure the carpal bones in the middle carpal joint. In a survey of 176 Standardbred horses undergoing carpal arthroscopy, only two antebrachial carpal joints had osteochondral fragments.

**Etiopathogenesis**

Osteochondral fragments of the carpus are induced by trauma. The history usually includes a sudden onset of carpal swelling. Certainly, some carpal chips with sharp areas of demarcation and healthy subchondral bone represent acute single-event failure; however, degenerative bone and cartilage, compatible with chronic injury, most often are found both on radiographs and at surgery. The subchondral bone associated with the carpal chip undergoes stress-adaptive remodeling because of repetitive loading. The bone becomes sclerotic and acquires increased stiffness.

In the third carpal bone, reduction in vascular channels can lead to ischemic necrosis of the subchondral bone. At surgery, degenerative bone appears discolored and brittle relative to the surrounding healthy bone. In racing Standardbreds, the prevalence of lameness was lower, 6.7% versus 45.4%, in horses with mild versus severe sclerosis of the third carpal bone. Resorption of the diseased bone predisposes development of a fracture at the junction of the compliant and noncompliant bone.

**Diagnosis**

Diagnosis is based on clinical signs, including lameness, painful response to carpal flexion, joint effusion, and reduced performance. A complete set of well-exposed radiographs, including the tangential view of the distal row of carpal bones and flexed lateral projections, is needed. Occasionally, the tangential view of the proximal row of carpal bones is required for diagnosis. If a carpal chip is found, radiographs of the contralateral carpus are recommended, because it is common for fragments to be present bilaterally (Fig. 96-1).

When a carpal chip is identified on a radiograph, it is important to document it as the cause of lameness, particularly in nonracing breeds, because it can represent an incidental finding. Intra-articular anesthesia in most cases confirms the associated joint as the source of lameness. Some horses become lame in the contralateral forelimb after anesthesia because of the presence of bilateral carpal chips.

When local anesthesia of the proximal suspensory region is induced, anesthetic may be injected into the palmar recesses of the carpometacarpal joint, anesthetizing both the carpometacarpal and middle carpal joints. Therefore, the relationship between the palmar recesses of the carpometacarpal joint and the proximal suspensory ligament...
should be considered when inducing local anesthesia in this area. Because of this, anesthesia of the middle carpal joint should be induced before the high palmar block if carpal lameness is suspected. Alternatively, the two-point high palmar block (see Chapter 74) is recommended for regional anesthesia of the proximal metacarpal region, because it prevents the anesthetic agent from entering the carpus.1

**Case Selection**

Most carpal chips are of clinical importance in racing breeds, and arthroscopic surgery to remove osteochondral fragments in the carpus is the treatment of choice. Factors that should be considered before chips are removed are the degree of lameness, the amount of degenerative change seen on the radiographs or lack thereof, previous intra-articular therapy, racing or training history, and economic concerns. Horses with carpal chip fractures are usually sound or mildly lame when jogged in hand, if examined a few days after the injury. If moderate or severe lameness is present, other conditions, such as slab fracture, moderate-to-severe cartilage damage, intercarpal ligament injury, or sepsis are suspected.

The radiographic findings of enthesiophytosis and subchondral bone lysis are associated with cartilage and subchondral bone damage at surgery (see Fig. 96-1). In one study, subchondral lysis of the radial carpal bone was associated with both osteochondral fragmentation and additional cartilage injury.13 In another study, horses with cartilage degeneration involving more than 30% of the articular surface of the affected bone (Fig. 96-2) had reduced postoperative performance.30

Factors associated with reduced racing prognosis postoperatively include repeated joint injection, reduced response to joint injection, injury early in training, and a poor preoperative racing record. These factors, coupled with economic considerations, are important in the surgeon’s case selection and the owner’s willingness to have surgery performed.

**Treatment**

The horse is positioned in dorsal or lateral recumbency based on the site of the lesion and the surgeon’s preference. If bilateral carpal arthroscopy is planned, or if both sides of a joint are to be examined, the author prefers to place the horse in dorsal recumbency with the limbs suspended from a rack or the ceiling. Antebrachiocarpal joint injury often occurs on both the lateral and medial sides simultaneously, and thus dorsal recumbency is usually selected.

The standard arthroscopy portals for the antebrachio-carpal and middle carpal joints are between the common digital and extensor carpi radialis tendons (lateral portal) and medial to the extensor carpi radialis tendon (medial portal). Portal locations for instruments and the arthroscope are determined by the lesion location, with the arthroscope portal placed farthest from the lesion.16 The portals are made large enough to allow egress of fluid without the accumulation of fluid in the subcutaneous space (approximately 6 to 8 mm). Large portals should be avoided or adequate joint distention will be difficult to maintain. If gas is used as the arthroscopic medium, the portals should be very small and only allow access of the arthroscope and instruments.

Once the osteochondral fragment is identified, it is partially loosened with an elevator if needed, grasped with Ferris-Smith rongeurs, and removed through the instrument portal. Diseased cartilage and subchondral bone are removed with a curet. The lesion is debrided, minimizing the amount of cartilage removed, especially in weight-bearing areas of

---

**Figure 96-1.** Dorso medial to palmarolateral oblique radiograph of the carpus of a Thoroughbred with an osteochondral fragment of the distal lateral aspect of the radius. Note the enthesiophyte formation and subchondral lysis consistent with osteoarthritis.

**Figure 96-2.** Arthroscopic view of the distal aspect of the radial carpal bone with moderate cartilage damage (grade II) and an osteochondral fragment. A greater than 30% loss of cartilage is associated with reduced postoperative performance.
Débridement of partial-thickness cartilage lesions adjacent to the fragment is avoided unless the cartilage is detached from the underlying subchondral bone. An exception to this is partial-thickness cartilage injury overlying diseased subchondral bone (e.g., radial facet of the third carpal bone), which is typically debrided.

Aftercare
The postoperative use of intra-articular or intravenous hyaluronan and intramuscular or intra-articular polysulfated glycosaminoglycan (Adequan) varies among surgeons. The author’s standard postoperative instructions for routine osteochondral carpal arthroscopy consists of 2 weeks of stall rest, 2 weeks of stall rest with hand-walking, and 2 weeks of pasture exercise, continued hand-walking, swimming physiotherapy, or a combination thereof. On occasion, a longer period of rest is given if substantial lameness or marked cartilage injury was present at the time of surgery. Bandaging is carried out until sutures are removed at approximately 12 days after the surgery.

Prognosis
A scale has been developed to grade cartilage injury observed at surgery. Grade I is minimal articular cartilage fibrillation or fragmentation extending no more than 5 mm from the fracture site. Grade II represents articular degeneration, including up to 30% of the articular surface of the bone. Grade III indicates loss of 30% to 50% of the articular surface. Grade IV represents severe loss of bone and cartilage associated with the fracture.10

Postoperative results of carpal arthroscopy for osteochondral fragments depend on the degree of cartilage injury observed at surgery. In the study by the author, horses with minimal to no cartilage injury (grades I or II) had a 72.8% chance of returning to racing at a level equal to or better than that before injury. Horses with cartilage damage greater than 30% of the visible surface of the affected bone (grades III or IV), there is only a 53.5% chance of return to racing at a level equal to or better than that before injury.12 In a survey of carpal arthroscopy in racing Standardbreds, 74% returned to racing after surgery and 61% raced at or above their previous level.12 In another survey from Japan, 82.6% of racing Thoroughbreds returned to racing after arthroscopic debridement, which is better than results in North America. A likely reason for the discrepancy is the higher percentage of antebrachio carpal joint injuries with little additional cartilage injury in the Japanese study.11 It is the author’s experience that cartilage injury is greater and the prognosis worse with chip fractures of the middle carpal versus the antebrachio carpal joint.

SUBCHONDRAL LUCENCY OF THE THIRD CARPAL BONE

Etiopathogenesis
Subchondral lucency or crush fracture of the third carpal bone is a common injury in racing breeds. It might be a prelude to slab fracture of the third carpal bone. Repetitive loading of the third carpal bone during training and racing leads to increased sclerosis of the radial facet, degeneration of the articular cartilage, and in some cases, loss of support from the subchondral bone. Subchondral lucency significantly influences the degree of carpal lameness in Standardbreds.12

Diagnosis
Clinical signs include lameness, reduced performance, and mild-to-moderate effusion of the middle carpal joint. Affected horses improve with intra-articular anesthesia of the middle carpal joint. A well-exposed tangential (skyline) projection of the third carpal bone is required for diagnosis. Radiographic signs include both sclerosis and lysis of the radial facet of the third carpal bone. In one study of racing Standardbreds and Thoroughbreds that improved after intra-articular anesthesia of the middle carpal joint and showed minimal to no degenerative changes on radiographs, 80% had cartilage damage, an incomplete fracture, or a crush fracture of the radial facet of the third carpal bone.18 Radiographs of the contralateral carpus should be taken because disease affecting both carpi is not uncommon.

Treatment
Some horses respond to intra-articular therapy but many do not; therefore, arthroscopic debridement is the treatment of choice.19 The articular cartilage often acquires partial- to full-thickness injury (Fig. 96-3). Removal of the abnormal cartilage reveals brittle, yellow-discolored, diseased subchondral bone and occasional fractures. In some cases, the mechanical strength of the cartilage and bone is poor, and the arthroscopic probe sinks into the subchondral plate. The abnormal cartilage and bone are completely removed. If a dorsal rim remains on the third carpal bone, it is typically removed (Fig. 96-4). Prognosis for return to racing for horses with arthroscopic debridement of such lesions is 89%.19

Figure 96-3. Arthoscopic view of the middle carpal joint of a 3-year-old racing Standardbred with a focal defect in the weight-bearing surface of the radial facet of the third carpal bone. On a tangential radiographic projection, subchondral lucency of the radial facet was seen.
MEDIAL PALMAR INTERCARPAL LIGAMENT INJURY

Etiopathogenesis

Diagnosis of partial or complete disruption of the medial palmar intercarpal ligament (MPICL) has become possible because of the use of arthroscopy in equine surgery. The medial and lateral palmar intercarpal ligaments prevent dorsal displacement of the middle carpal joint. The frequency of injury to this ligament ranges between 8.7% and 70%. Medial palmar intercarpal ligament injury can occur alone or with other types of carpal injury, including osteochondral fragments and cartilage damage. One report found no association between intercarpal ligament injury (ICL) and cartilage injury.

Diagnosis

Clinical signs of MPICL injury include moderate lameness and joint effusion. In acute cases, no radiographic signs specific to this injury are seen. In chronic cases, new bone formation on the distal dorsal aspect of the proximal row of carpal bones can be seen, which is related to a degree of joint instability. Intercarpal ligament injury is suspected by evaluation of clinical signs, absence of radiographic abnormalities, and response to middle carpal joint anesthesia. Ultrasonographic evaluation of the MPICL has been described in the standing horse.

Confirmation of diagnosis is achieved through arthroscopic evaluation. Ligament disruption can be partial or complete (Fig. 96-5). A grading scale of injury from I to IV has been suggested. Grade I indicates rupture or fraying of a small number of fibers; grade II, rupture of up to one third of the ligament fibers; grade III, rupture of two thirds; and grade IV, complete rupture of the ligament. Mild (grade I) tears can be incidental findings at surgery and might not be associated with lameness.

Carpal Slab Fractures

Etiopathogenesis

The third carpal bone is a common site for injury. Fracture types include osteochondral fragments, corner fractures, small and large frontal plane slab fractures, and sagittal slab fractures. Carpal slab fractures occur most often in the frontal plane of the radial facet of the third carpal bone. Fracture of the radial facet of the third carpal bone also can occur in the radial, fourth, and intermediate carpal bones. Because the radial facet of the third carpal bone undergoes stress-adaptive remodeling during race training, repetitive loading of this area consistently leads to fracture in this location. Additionally, subchondral lucency, cartilage injury, and incomplete fractures often occur in this area.

Diagnosis

Horses with complete slab fractures of the third carpal bone have moderate to severe lameness, are reluctant to flex the carpus, and exhibit joint effusion. The right forelimb is more often affected in Thoroughbreds, but both forelimbs are equally affected in Standardbreds. Horses with incomplete slab fractures have variable lameness and usually little joint effusion.
Radiographs, including the skyline projection, confirm the diagnosis and aid in the choice of treatment. Fragmentation at the articular margin of the middle carpal joint, third carpal bone sclerosis, and lysis can be present; these usually indicate advanced disease. Diagnosis of incomplete fractures is more difficult because localizing signs can be absent. Careful lameness examination, diagnostic anesthesia, well-positioned and well-exposed radiographs, and sometimes nuclear scintigraphy are necessary for diagnosis. Once a diagnosis is established, radiographs of the other carpus are obtained because bilateral slab fractures or other carpal disease can be present. Bilateral slab fractures occur most commonly in Standardbreds.

**Treatment**

Treatment options for complete slab fractures include removal of the slab or surgical repair of the fracture with interfragmentary bone screws placed in lag fashion. Surgery is recommended for all horses, even those to be retired from racing. Conservative management of complete slab fractures often results in moderate to severe osteoarthritis. Removal of slab fractures is recommended when thin fragments (less than 10 mm thick) are present or if there is significant loss of articular cartilage associated with the fracture.

In many complete slab fractures, there is a wedge-shaped piece of bone and cartilage present where the fracture enters the middle carpal joint (Fig. 96-6). This fragment might not be obvious on the preoperative radiographs. The consequence of this fragment is the potential loss of a large area of cartilage at the fracture site; in such cases, removal of the slab fracture may be elected. If cartilage loss is minimal or if the fracture is more than 10 mm thick or incomplete, compression of the fracture fragments with one or more bone screws is preferred.

Successful management of incomplete fractures is possible with rest alone; however, some horses refracture when they return to racing and eventually require surgery.

**Surgical Technique**

Internal fixation of frontal or sagittal slab fractures can be accomplished using arthroscopic or arthrotomy techniques. Arthroscopy has considerable advantages over arthrotomy in the management of third carpal slab fractures and is considered the treatment of choice. Arthroscopy provides a more complete examination of the joint and facilitates débridement of the fracture gap, but it is technically more difficult to properly orient the implant, and experience is necessary with the arthroscopic technique.

In _arthrotomy_ repair, the horse is positioned in lateral recumbency with the affected limb uppermost or in dorsal recumbency. The lateral portal is used to position the arthroscope for examination of the medial aspect of the middle carpal joint. The medial portal is used to débride the fracture. The joint is held in extension because this position opens the fracture gap.

Fracture hematoma and fragments of bone are removed. Subsequent flexion of the joint reduces the fracture. Hypodermic needles are placed at the lateral and medial extent of the fracture in the middle carpal joint and into the carpometacarpal joint to identify the borders of the fracture. The locations of the hypodermic needles and the reduction of the fracture are confirmed arthroscopically (Fig. 96-7). A 2.5-mm drill bit, oriented perpendicular to the dorsal surface of MCIII, is placed through a separate incision in the carpometacarpal joint to identify the borders of the fracture. The 3.5-mm screw also provides ample compression (Fig. 96-9).

**Fixation** technique is used to place a 3.5- or 4.5-mm cortex screw in lag fashion. During the placement of the marker bit and screw, it is important to maintain the carpus in flexion to provide adequate reduction.

If _arthrotomy_ is elected, an incision is made into the middle carpal joint over the radial facet of the third carpal bone just medial to the extensor carpi radialis tendon. The fracture line is identified and débrided. Orientation of the drill bit is easier with an arthrotomy compared with the arthroscopic technique. The bit should be positioned perpendicular to MCIII and in the center of the fracture fragment (if only one screw is required). The 3.5-mm AO ASIF system is used for most fractures and provides ample compression (Fig. 96-9). The 3.5-mm system has the advantage of easier placement of single or multiple screws because of its smaller size (Fig. 96-10). There is reduced risk of splitting the fracture fragment compared with the 4.5-mm system. The 3.5-mm screw also has a smaller head, which interferes less with the soft tissues over the carpus. Because of these features, 3.5-mm screws are used in thinner slabs. The 4.5-mm system is used for fractures that are large, typically involving both the radial and intermediate facet of the third carpal bone or other carpal bones (Fig. 96-11).
Careful intraoperative monitoring with radiographs or image intensification is required regardless of whether arthroscopy or arthrotomy is chosen.

Displaced sagittal slab fractures should be repaired with 3.5-mm screws. These fractures are usually located on the medial aspect of the third carpal bone. Both arthroscopy and arthrotomy techniques can be applied with intraoperative monitoring to guide placement of the implant. The surgical approach depends on location of the fracture. Screw placement should avoid contact of the screw head with the second carpal bone, which can cause lameness.

The presence of additional carpal pathology is typical in cases of third carpal slab fracture. A trough of cartilage and bone is usually present at the site where the fracture breaks...
into the middle carpal joint. When a trough is left on the
parent portion of the bone behind the slab, lag screw fixa-
tion is still an option. The slab is fixed to the parent portion
of the bone with one or two screws, and the proximal 4 mm
of the slab is removed with a chisel; depending on the
size of the trough and the surgeon’s preference, the proximal
4 mm could be left in place. By removing the articular
surface, contact with the opposing bone is prevented,
allowing undisturbed healing of the fracture. Additional
pathology seen in the joint includes distal radial carpal bone
chips, cartilage damage, and medial palmar intercarpal
ligament injury.

Aftercare
Aftercare is routine, with bandaging for several weeks and
a slow, gradual return to work. Most horses require approx-
imately 4 months of recovery before returning to race
training. Prognosis differs among breeds, with 77% of
Standardbreds and 65% of Thoroughbreds returning to
racing after surgery. Many horses return to racing at a lower level of performance.\textsuperscript{28,29}

**MULTIFRAGMENT FRACTURES**

**Etiopathogenesis**

Multifragment fractures typically occur after kicks, falls, or collisions. Such injuries can also occur during racing. Non-weight-bearing lameness and carpal swelling are typical. The horse exhibits angular limb deformity and carpal hyperextension because of carpal collapse.

**Diagnosis**

Radiographs confirm the presence of multiple fracture lines involving several bones. Most of these fractures involve the medial aspect of the carpus and can include the radial, intermediate, second, or third carpal bones or a combination thereof. The loss of support of the bone column on the medial aspect of the carpus typically causes a carpal varus deformity.

**Treatment**

First aid is aimed at reconstructing the bone column by placing palmar and lateral splints over a bandage. The inherent instability and articular nature of the fractures usually makes external coaptation with casts or splints inadequate for treatment, however. Most horses remain severely lame, develop pressure necrosis of the skin, and are at high risk for developing laminitis in the supporting limb with coaptation alone.

Realignment of the bone column by reconstruction of the carpal bones with screws is recommended. If the bone column cannot be re-established, carpal arthrodesis with bone plates should be considered (see Chapter 85). Any attempt to treat such an injury is a salvage procedure. For carpal reconstruction, an arthrotomy over the appropriate joint space is performed, and the carpal bones are reconstructed using 5.5-mm, 4.5-mm, and 3.5-mm screws. In some cases arthroscopic reconstruction is possible.

Proper reduction of the fracture fragments is paramount during the reconstruction of the bone column for weight-bearing and load sharing with the implants. Additionally, a reduction in the development of osteoarthritis is achieved. At surgery, additional fracture lines and fragments are often found, which complicate the procedure. Coaptation in a sleeve cast for 4 to 6 weeks is recommended postoperatively.

Carpal arthrodesis is performed when the bone column cannot be reconstructed or in the presence of severe osteoarthritis, angular limb deformity, or instability caused by the fracture or luxation. Partial or pancarpal arthrodesis can be performed, and a variety of implants have been used.\textsuperscript{12,31} For a more in-depth description of different arthrodesis procedures, please review Chapter 85.

**CARPAL HYGROMA**

**Etiopathogenesis**

Carpal hygroma is a subcutaneous swelling over the dorsum of the carpus. It is usually associated with a history of trauma to the region. Although the swelling is usually not infected, the potential for sepsis exists after drainage or injection, or both.

**Diagnosis**

Horses with sterile hygromas are not usually lame, but those with infected hygromas exhibit variable lameness depending on whether the area is draining. The skin is usually thickened. Purulent drainage is typical in infected hygromas, but joint involvement is rare.

Radiographs should be obtained to rule out bone involvement. Contrast radiography is helpful in determining joint or tendon sheath involvement and to outline the extent of the hygroma (Fig. 96-12). Filling of the joint by contrast medium from the hygroma in most cases is not expected because of the valve-like action of the tissues involved; therefore, communication between the joint and the hygroma is confirmed or ruled out through fluid injection into the middle carpal or antebrachiocarpal joint. An indirect filling of the hygroma confirms the communication. Ultrasonography helps to rule out the presence of a foreign body.

**Treatment**

Nonseptic carpal hygroma can be treated with rest, systemic and local anti-inflammatory agents, and bandaging. Hygromas that are refractory to treatment or that recur are treated with drainage and injection of corticosteroids or sclerosing agents as well as resection. Once sepsis is
established in the subcutaneous space, resolution is often difficult despite the use of lavage, drainage, and antimicrobial agents. When infection is present, resection of infected tissue is the treatment of choice.

**Surgical Technique**

The horse is placed under general anesthesia with the affected limb uppermost and the limb prepared for aseptic surgery. An elliptical incision is made over the hygroma and over a fistula, if one is present. The skin is reflected off the lining of the hygroma, retaining the subcutaneous tissue with the skin. Care is taken to avoid puncturing the hygroma. The dissection is continued to the fibrous layer of the carpal joint capsule and tendon sheaths of the extensor carpi radialis and common digital extensor tendons, and the hygroma is removed en bloc. Care is taken to avoid penetrating the carpal joints or tendon sheaths.

Once the hygroma is removed, excess skin is resected from the skin edges to reduce dead space. Two 6-mm Penrose drains are placed and secured to the top of the dead space and exited distally on the medial and lateral aspects of the incision. The subcutaneous tissue is secured to the joint capsule with multiple mattress sutures of absorbable material to decrease dead space. The subcutaneous tissue and the skin are closed routinely.

Elastic bandaging tape (such as Elastikon) is placed on the carpus directly over a sterile dressing as a pressure wrap. The limb is placed in a stack bandage followed by four layers of casting tape in which a polyvinylchloride splint is incorporated to the palmar surface. The casting tape and splint extend from below the elbow to the distal metacarpus. The cast bandage with splint effectively immobilizes the carpus and protects the skin incision during recovery from anesthesia and in the postoperative period.

Three days after surgery, or earlier if needed, the cast bandage is bivalved, and the dorsal portion is discarded. The wound dressing is changed, the stack bandage is replaced, and the palmar portion of the cast and splint is reapplied. The drains are removed 3 to 5 days postoperatively, and the splint is maintained for a total of 10 days. A bandage is maintained for 4 weeks after surgery. Antimicrobial and anti-inflammatory agents are used as needed. Hand-walking is initiated 1 month after surgery, and the horse is turned out to pasture or returned to exercise at 2 months.

**DISTAL RADIAL EXOSTOSIS**

**Clinical Signs**

Exostosis of the distal radius is a rare cause of lameness in horses. The development of exostosis on the caudal border of the distal radial physis causes a tenosynovitis of the carpal canal and irritation of the deep digital flexor tendon. Exostosis is differentiated from osteochondroma by its location and by histologic examination. Osteochondromas are present on the caudal border of the distal radial metaphysis typically 2 to 4 cm proximal to the distal radial physis. Exostoses are devoid of hyaline cartilage remnants, which are present in osteochondromas.

Regardless of the origin of the mass, the resultant tenosynovitis caused by both conditions results in both a weight-bearing and swinging-limb lameness. The horse often carries the affected limb slightly abducted at the trot, and the lameness generally worsens with carpal flexion. Effusion of the carpal canal can be difficult to detect without careful inspection of the lateral aspect of the limb in the distal third of the forearm. Lameness is improved after intrasynovial anesthesia of the carpal canal.

Radiography confirms the presence of the exostoses on the caudal aspect of the distal radial physis (Fig. 96-13). Exostoses are occasionally seen as an incidental finding on survey radiography. Clinical exostoses generally measure at least 10 mm off the caudal aspect of the radius. It is important to confirm the exostosis as the cause of lameness by intrasynovial anesthesia.

**Nonsurgical Management**

Management of carpal canal tenosynovitis is by intrasynovial injection of hyaluronan and corticosteroids. In the author’s experience, if the response to therapy is incomplete or short-lived, then surgical removal of the exostosis is the treatment of choice to remove the underlying cause of the tenosynovitis.

**Surgical Management**

Distal radial exostoses can be removed via carpal canal endoscopy, which represents the method of choice. The horse is positioned with the affected limb positioned uppermost and the forelimb and carpus prepared for aseptic surgery. The carpal canal is distended with lactated Ringer’s solution and the arthroscopic cannula is placed between the lateral digital extensor and the ulnaris lateralis tendons through a stab incision at a level of the proximal to the distal radial physis.

![Figure 96-13. Flexed lateral radiograph of the carpus of a 7-year-old Thoroughbred with an exostosis of the caudal aspect of the distal radial physis.](image-url)
The carpal canal is entered and a standard 4.0-mm 25-degree arthroscope is used for the examination. There is ample room within the carpal canal, and the arthroscope is usually positioned to examine the exostosis and any associated deep digital flexor tendon injury without difficulty. A needle is used to ascertain the proper location for the instrument portal distal to the arthroscopic portal. A 5-mm osteotome is used to loosen the exostosis from its bed. Care should be taken to remove the exostosis as close to its base as possible and not to completely dislodge it. The mass is grasped with a Ferris-Smith rongeur and removed. The associated bed can be further debrided with a rongeur or osteotome. Release of the carpal flexor retinaculum can also be accomplished via endoscopic guidance if constriction of the carpal canal is suspected.35

The canal is lavaged and the is skin closed with non-absorbable monofilament suture. Intraoperative radiographs are recommended to confirm that the entire exostosis was removed. A full limb bandage is used for recovery from general anesthesia. Postoperative recommendations include box stall confinement for 4 weeks and pasture turnout for 4 to 8 weeks thereafter.

Prognosis
Prognosis after removal of distal radial exostoses is good. In a clinical report, 9 of 10 horses returned to full athletic function after endoscopic removal of the exostosis. The remaining horse became sound after further intrasynovial medication with hyaluronan.34

ANGULAR LIMB DEFORMITIES
Angular limb deformities of the carpus occur commonly in foals. Valgus deformity is more common than varus deformity. Angular limb deformities of the carpal region can be caused by physeal dysplasia, joint laxity, and cuboidal bone hypoplasia or malformation.

Methods of treating angular limb deformities of the carpal region include splints, bandages, casts, growth retardation, and, most commonly, periosteal elevation and transection. Treatment varies depending on the age of the horse and the cause of the deformity. Treatment options are discussed in detail in Chapter 89.

ACCESSORY CARPAL BONE FRACTURES
Etiopathogenesis
Fracture of the accessory carpal bone occurs in Thoroughbred horses that race over fences, but it can be seen after collisions or falls in any breed. Relative to other carpal injuries, accessory carpal bone fractures are rare, representing 2% of all carpal fractures.37 In a survey of Thoroughbred yearlings radiographed prior to sale, accessory carpal bone fractures were found in 0.4% of the horses.3 Because of its location on the palmar aspect of the carpus and its multiple ligamentous attachments, the accessory carpal bone undergoes intense loading during extension of the carpus.

The preponderance of frontal plane fractures is likely caused by avulsion of the bone by its palmar attachments during carpal loading. Other suspected causes of accessory carpal bone fractures include compression between the radius and MCIII and direct trauma. It is typical for a small degree of comminution to be present at the fracture site in frontal plane fractures.37 Nonarticular chip fractures and comminuted fractures are occasionally diagnosed.38,39

Diagnosis
Acute, severe lameness is typical. The carpus can be held in a somewhat flexed position to reduce loading. Carpal canal effusion might be present, but carpal joint effusion might be absent unless there is an articular component to the fracture.

Diagnosis is confirmed through radiographic examination. In acute fractures, displacement is usually present, although nondisplaced fractures occur. In nondisplaced fractures, another set of radiographs should be taken 10 to 14 days after injury. Nuclear scintigraphy and, if available, computed tomography are helpful in defining the fracture in detail. In chronic fractures, fragment edges are indistinct.

Treatment
Treatment options include conservative management or surgical reconstruction and compression with bone screws or plates. Conservative management has varying success. Stall rest for 3 months followed by turnout at pasture for 3 to 9 months is recommended. Of 19 horses with accessory carpal bone fractures, 17 were treated conservatively with rest for 3 to 6 months and two had internal fixation. All 11 horses available for follow-up were sound, and seven had returned to racing.37

Surgical repair with bone screws has been most often attempted in simple vertical fractures. Because of the location, the concave shape of the accessory carpal bone, and the narrow space for error in screw placement, attempts at surgical repair are infrequent. These difficulties, coupled with the low incidence of the injury, make the decision between conservative and surgical management difficult. In one study, vertical fractures were treated experimentally, followed by treatment with immediate or delayed repair with bone screws or conservative management.40 Three horses treated conservatively were still lame 6 months later, whereas all horses that had been surgically treated were sound at 6 months. Wound infection and screw breakage were reported complications. Another clinical study reports success with surgical management of vertical fractures with bone screws.39

The application of two four-hole 2.7-mm dynamic compression plates (DCPs) perpendicular to the vertical fracture plane resulted in solid bone union within 3 months and return of the horse to full athletic use.48 The plate counters the tensile forces that displace the fracture, and the compression exerted across the fracture plane aids healing. The same result was achieved with a cervical fusion plate (Synthes, Paoli, Pa) applied to the lateral surface of the fractured accessory carpal bone48 (Fig. 96-14).

Although conservative management of accessory carpal bone fractures can result in complete return to athletic soundness in fractures of many months’ to years’ duration, complete bone union is not usually present. In chronic fractures, the potential for carpal canal syndrome exists and should be evaluated during the examination.42 Therefore, because surgical management of simple vertical fractures has
the potential to return the horse to athletic soundness with minimal callus formation and good bone union, it is the recommended treatment.

**LUXATION (SUBLUXATION)**

**Etiopathogenesis**

Carpal luxations are traumatic events caused by falling with one limb wedged in a fixed position, as a result of a car accident, or through a precise kick at a collateral ligament. Other causes are speculative because often the animal is found in the pasture with an obvious luxation whose origin was not observed.

**Diagnosis**

The animal might be presented with an obvious deformity in the carpus resulting in an abnormal position of the limb distal to the carpal region. In this instance, the diagnosis is obvious from radiographs (Fig. 96-15). Alternatively, the animal might bear weight on the limb but show a marked lameness. Standard radiographs might show some small bone chips in the periarticular region as the only abnormality. If the luxation is in association with skin trauma, crepitus is recognized in the periarticular soft tissues. A definitive diagnosis of joint involvement with the wound is made through arthrocentesis and stress radiographs under general anesthesia.

**Treatment**

Management of luxations may be carried out conservatively or through surgical intervention. Conservative treatment involves cast application for 3 months with two or three cast changes. During this time, the ruptured periarticular soft tissues heal by fibrosis. Depending on which joint is involved, decreased carpal flexion is the result. Careful management of the convalescent period helps in restoring a useful animal. Coaptation should only be considered if the bone column is intact and the bone column does not collapse during weightbearing.

Surgical management through partial or pancarpal arthrodesis is an option and is discussed in Chapter 85. Proximal fractures of the second or fourth metacarpal bone cause subluxation of the carpometacarpal joint. Small plates to repair these fractures are recommended to overcome the tension forces of the collateral ligaments, even in small foals. The author’s experiences with coaptation or screw fixation alone have been disappointing. Plate fixation of proximal fractures of the small metacarpal bones is discussed in detail in Chapter 95.

**CORONATION (COURONNEMENT)**

**Etiopathogenesis**

Coronation refers to a severe soft-tissue injury of the dorsum of the carpus that occurs after a fall. It is characterized by the loss of skin over the carpus, and in more-severe cases, the
wound involves the synovial sheaths of the extensor carpi radialis, common digital extensor tendons, or one of the carpal joints.

Diagnosis
Physical signs of injury are obvious, with a flap or degloving wound present over the dorsum of the carpus (Fig. 96-16). Entry into the tendon sheaths or joints might be obvious, but puncture wounds might go unnoticed.

If synovial involvement is suspected, a needle should be placed into the carpal joint or tendon sheath at a site distant from the wound after aseptic preparation and the structure distended with sterile saline to detect any defects. Care must be taken to avoid entry through traumatized or infected tissue to prevent inoculation of the synovial structure with bacteria. For the tendon sheath, a proximal location is chosen, and for the carpal joints, the palmar outpocketings may be used. Any draining fluid obtained is collected and submitted for cytologic examination and culture and susceptibility testing. Occasionally, the extensor carpi radialis or common digital extensor tendon is ruptured as well.

Radiographs should be obtained after cleaning the wound to assess bone injury and identify additional debris, especially gravel. Contrast radiography can be used to identify communications between the synovial structures and the wound. The use of ultrasonography is limited because of subcutaneous emphysema from the wound.

Treatment
Treatment consists of management of the wounds and any involved synovial structure. Wound management and management of synovial infections are discussed in Chapters 26 and 88, respectively. Some specific issues of management of these wounds deserve mention here (Fig. 96-17, A).

The author prefers to close acute wounds into synovial structures after lavage and intra-synovial antimicrobial therapy unless severe contamination exists. A 1- to 2-mm rim of skin is sharply dissected along the skin defect, followed by careful sharp surgical débridement of the deeper tissues (Fig. 96-17, B and C). In cases where the joint capsule is opened as well, intra-articular lavage is mandatory. This can be accomplished through needles placed from the palmar aspect of the carpus (Fig. 96-17, D) or from the dorsolateral or dorsomedial aspect of the carpus (Fig. 96-17, E).

The joint capsule is subsequently closed using simple interrupted sutures of a 2-0 monofilament absorbable suture material.

After implantation of one or two drains the skin is closed in routine fashion (Fig. 96-17, F). Delayed wound closure is sometimes necessary to identify the extent of injury and allow débridement. The use of splints, cast bandages, and casts is usually necessary to provide immobilization for wound healing. Supportive therapy such as repeated joint
lavage, anti-inflammatory agents, and antimicrobial agents varies with the type and severity of the wound. Horses can return to full athletic activity after injuries that involve superficial structures. Wounds that involve the tendon sheaths, joint, or carpal bones have a reduced prognosis, which is determined by the extent of the wound and use of the horse. Even wounds that have had significant loss of tissue over the dorsum of the carpus can heal and provide a satisfactory outcome if the synovial structures respond appropriately.

CHAPTER 97

Radius and Ulna
Jeffrey P. Watkins

The equine antebrachium consists of the radius and ulna in conjunction with the muscles that flex and extend the carpus and digit. The radius is the major weight-supporting bone in the antebrachium. The olecranon, by serving as the insertion site of the triceps muscle, acts as the lever arm during elbow extension. The primary indications for surgical intervention in this area are caused by traumatic events that result in fracture of either the ulna or the radius.

FRACTURES OF THE ULNA
Fractures of the ulna are relatively common in foals and adult horses. A wide variety of fracture configurations occur, and most are amenable to open reduction and internal fixation. The treatment of choice is fracture fixation using a bone plate applied as a tension band. Provided complications are not encountered, the prognosis is favorable for a return to full function.

Anatomy
The ulna has two components, the body and the olecranon. The body of the ulna extends distad from the level of the proximal radial physis. It is triangular in cross section and tapers distally, essentially ending in the mid-diaphyseal region of the radius. It is closely adherent to the radius, and distal to the interosseous space it is fused to the caudal cortex of the radius. Functionally, it serves as the distal attachment of the lever arm through which the triceps muscle functions.

Proximal to the body of the ulna is the olecranon. The olecranon is concave medially and has a proximal tuberosity for muscle attachment. Tendinous insertions on the olecranon tuberosity, principally by the triceps brachii muscle, provide elbow extension during locomotion. Equally important, by extending the elbow during standing, the triceps apparatus allows extension of the carpus through engagement of the stay apparatus of the forelimb. The olecranon is also an important component of the cubital joint, with articular cartilage present in the proximal aspect of the trochlear notch. In the distal aspect of the trochlear notch there is a synovial fossa, which is devoid of articular cartilage.

Foals have a physis in the proximal olecranon. Because the separate center of ossification of the physis is not involved in formation of a joint, it is termed an apophysis. Although growth at the olecranon physis is responsible for the ultimate size of the olecranon tuberosity, disturbances of physeal growth following injury or fracture repair are well tolerated and do not result in disability. However, because growth occurs at the proximal radial physis, the ulna must be able to displace proximad relative to the radius to maintain congruency between the humeral condyle and the trochlear notch of the olecranon.

Pathogenesis
A direct blow from a kick or a fall causes most fractures of the ulna. A common history includes injury during halter training of weanling foals. Often the fracture occurs when the foal rears up and falls onto its side. The body of the ulna or, more commonly, the olecranon fractures, and fragments are displaced during contraction of the triceps muscle when the foal jumps to its feet.

Ulnar fractures have been classified. The most common configuration is for the fracture to traverse the caudal one third to one half of the physis, enter the metaphysis, and break into the proximal aspect of the trochlear notch near the anconeal process (type 1b) (Fig. 97-1). Less commonly, the fracture breaks out the cranial cortex of the olecranon proximal to the anconeal process and remains nonarticular (also type 1b). Occasionally, comminution occurs at the anconeal process.

Other configurations include physeal separations (type 1a), most common in neonates; transverse fractures entering the trochlear notch near its midpoint (type 2); distal olecranon–proximal ulnar body fractures, which usually have an oblique configuration traversing the bone in a proximal and cranial direction to enter the distal aspect of the trochlear notch (type 5); and comminuted fractures (type 4). Type 3 fractures—nonarticular, nonphyseal fractures of the olecranon extending from the caudal cortex to the cranial cortex proximal to the anconeal process—are rare.

Figure 97-1. Mediolateral radiograph of type 1b, articular olecranon fracture.
The degree of soft tissue injury varies greatly. Contusions resulting from a kick are often accompanied by a skin wound at the site of impact. These wounds might communicate directly with the fracture, and if the fracture is articular, joint sepsis can develop secondary to bacterial colonization of the fracture. Displacement of the fracture is another indicator of the degree of soft tissue damage. Marked displacement indicates disruption of the aponeurosis of the ulnar head of the deep digital flexor muscle laterally and the ulnar head of the flexor carpi ulnaris muscle medially.

**Diagnosis**

The affected limb has a dropped-elbow appearance, because the carpus cannot be fixed in extension. Depending on the amount of displacement, the elbow might appear only slightly dropped, with the carpus held in flexion, the limb placed slightly cranial, and the toe touching the ground. With severe displacement, marked dropping of the elbow along with carpal flexion is evident (Fig. 97-2). The differential diagnosis for a dropped elbow stance includes ulnar fracture, humeral fracture, and radial neuropathy.

Soft tissue swelling is usually not severe in most ulnar fractures and is localized to the caudolateral aspect of the proximal antebrachium. This is distinct from humeral fractures, in which the swelling is typically much greater and best visualized by standing in front of the horse and comparing the relative thickness of the humeral regions on affected and unaffected sides. Pain on deep palpation and manipulation of the olecranon aids in localizing the fracture.

Definitive diagnosis is based on radiographic documentation of the fracture. Best detail of the area is obtained with a medial to lateral projection and the beam obliques slightly cranial to caudal. When the affected limb is extended cranially, complete visualization of the cubital joint and olecranon is possible, and the fracture configuration and location can be determined. With type 1b fractures, it is important to visualize the anconeal process to delineate comminuted fragments. A cranial to caudal radiograph is necessary to detect concurrent injury to the proximal radius (Fig. 97-3). A contrast arthrogram determines the extent of communication between a soft tissue wound and an articular fracture.

**Treatment**

**First Aid**

Initial care for horses with fracture of the ulna accompanied by a wound should include appropriate wound therapy, removal of hair at the wound margins, and careful cleansing and débridement, followed by application of a sterile bandage to prevent further contamination before surgery. Systemic broad-spectrum bactericidal therapy should be initiated immediately.

It is important to ascertain the extent of soft tissue trauma. Fortunately, many wounds encountered with olecranon fractures are superficial and do not markedly affect therapy or prognosis. However, deep wounds that communicate with the fracture, particularly articular fractures, dictate aggressive therapy. Therapy for open articular fractures includes administration of intra-articular antimicrobial drugs. In addition, antimicrobial-impregnated polymethylmethacrylate (PMMA) beads placed into the depths of extensive soft tissue wounds help to reduce bacterial contamination before open reduction and internal fixation of the fracture.

**Figure 97-2.** Photograph demonstrating the typical dropped elbow stance in a foal with a displaced olecranon fracture.

**Figure 97-3.** Craniocaudal radiograph demonstrating a Salter-Harris type III fracture of the proximal radius (arrowheads), which occurred in conjunction with a fracture of the ulna (arrows).
Many horses with displaced fractures cannot engage their stifle apparatus and therefore are unable to support weight on the affected limb. If so, a splint is applied once wound therapy is complete. Although it is not possible to splint the fracture per se, splinting the carpus in extension allows weight to be supported on the affected limb. This markedly reduces the horse’s anxiety and minimizes fatigue of the contralateral limb before internal fixation.

The splint should consist of rigid material applied over a well-padded full-limb bandage. Splints are fashioned from schedule 40 polyvinylchloride (PVC) pipe; an appropriate length is cut from a 15-cm (6-in.) diameter pipe and split longitudinally, using one third of the pipe’s circumference. The splint should extend from the ground to the proximal antebrachium and is affixed to the bandage with nonelastic adhesive tape. Additional padding at the proximal aspect of the splint prevents soft tissue damage near the fracture site.

Nonsurgical Management

Conservative therapy has been advocated for nondisplaced, nonarticular fractures of the ulna (nondisplaced types 3 and 4). Conservative therapy includes strict stall confinement. If the patient does not bear full weight on the limb, a full-limb splint is applied. Functional soundness was reported in 7 of the 10 horses with type 5 fractures managed conservatively. Poor results are achieved following conservative therapy for other fracture configurations.

Horses with nondisplaced, nonarticular fractures that are managed conservatively have a prolonged convalescent period because of the instability of the fracture. Healing is slow, and lameness is protracted. Although type 5 fractures do not violate the articular surface of the cubital joint, they communicate with the synovial cavity. Therefore, inflammatory mediators released into the joint from the fracture have detrimental effects on the articular cartilage and lead to degenerative articular changes. Despite the inherent risk of surgery and anesthesia, surgical treatment is preferable, and the primary determinant for choosing conservative therapy over surgical therapy is economics.

Surgical Management

Open reduction and internal fixation is the treatment of choice for articular or displaced fractures of the ulna. By using the tension-band principle, stable fixation of nearly all fracture configurations can be achieved with minimal complications and a favorable prognosis. Tension-band fixation can be accomplished using a plate applied to the caudal aspect of the ulna or by using tension-band wire fixation.

The surgical approach to ulnar fractures has been described. It is advisable to curve the skin incision proximally to avoid the point of the elbow. When possible, wounds should also be avoided when approaching the fracture. Once the skin and subcutaneous fascia have been incised, deep dissection between the ulnaris lateralis and ulnar head of the deep digital flexor tendon exposes the caudal and lateral aspects of the ulna.

Distally, the ulna is exposed for plate application by subperiosteal dissection. Proximally, the caudal and lateral aspects of the olecranon are closely invested in the dense fibrous connective tissue aponeuroses of the ulnar head of the deep digital flexor and flexor carpi ulnaris muscles. Sharp dissection of the fibrous connective tissue attachments from the olecranon is necessary for plate application. Additional dissection exposes the proximal aspect of the olecranon tuberosity for fixation of type 1 and 3 fractures. In these cases, the insertion of the triceps is sharply divided in the sagittal plane of the cranial olecranon and dissected abaxially for the approximate width of the fixation appliance.

Once the bone is exposed, the fracture hematoma is evacuated and the fracture line debrided of all fibrin or, in chronic cases, fibrous tissue. Assessment of the bone at this time might reveal hairline cracks in the ulna that might not have been evident radiographically. If the anconeal process is comminuted, the fracture is opened and the fragment is removed through the fracture gap. In displaced fractures, reduction is accomplished by grasping the olecranon process medially and laterally with a large pointed reduction forceps (Synthes, Paoli, Pa) and applying caudal and distal traction with the limb held in extension.

A soft aluminum template is used to provide a model for plate contouring. The plate is positioned to allow screw engagement of a minimum of five cortices on either side of the fracture. Usually a combination of 4.5- and 5.5-mm cortex screws in conjunction with a narrow limited-contact dynamic compression plate (LC-DCP) or dynamic compression plate (DCP) is used for fixation. In large patients or more comminuted fractures, a higher proportion of 5.5-mm cortex screws are used, and a broad LC-DCP or DCP may be chosen. In adult horses with comminuted fractures, double plate fixation with a broad LC-DCP or DCP applied caudally and a narrow LC-DCP or DCP applied laterally may be necessary.

The appropriately contoured plate is applied with the fracture held in reduction by positioning one screw proximal and another screw distal to the fracture. The initial screw is placed in the proximal fragment using the neutral drill guide. This screw is not tightened completely, and the plate is displaced distally before placing the screw in the distal fragment using the load drill guide. Tightening of these two screws compresses the fracture. Over-compression of minimally displaced fractures with comminution at the articular surface can result in fragment displacement. Therefore, screws should be applied in the neutral position with comminuted fractures.

At this point in the repair, an intraoperative lateromedial radiograph should be taken to assess the fixation (Fig. 97-4). The intraoperative radiograph can be used to evaluate the adequacy of reduction and screw position and as a guide for directing and gauging the approximate length of the remaining screws.

If further compression is needed, an additional screw on either side of the fracture can be placed in the load configuration. Before tightening these additional load screws, the previously placed screw in the same fragment should be loosened slightly. The remainder of the screws are placed in the neutral position.

Screw placement in the proximal fragment must avoid penetrating the concave medial cortex. Screws at the level of the trochlear notch should not penetrate into the joint.

Distally, screws should not engage the caudal cortex of the radius in foals. If the body of the ulna is transfixed to the
subluxation was evident radiographically and at necropsy. Even though subluxation was not a clinical problem in foals that were 7 months old or older at the time of surgery, even though subluxation of the cubital joint occurs, resulting in elbow dysplasia. The age at which it is safe to engage the caudal cortex of the radius and ulna was transfixed, it appeared that a type 1b fracture. Plate position and fracture reduction before cortex screws are placed in lag fashion through the plate into the cranial cortex of the olecranon in a type 1b fracture.

Figure 97-4. Intraoperative lateromedial radiograph documenting plate position and fracture reduction before cortex screws are placed in lag fashion through the plate into the cranial cortex of the olecranon in a type 1b fracture.

radius, growth of the proximal radial epiphysis forces the anconeal process into the humeral condylar notch, and subluxation of the cubital joint occurs, resulting in elbow dysplasia. The age at which it is safe to engage the caudal cortex is not well defined. In one study, there was growth at the proximal radial physis with relative displacement of the ulna until 18 months of age. However, in another study in which the radius and ulna were transfixed, it appeared that subluxation was not a clinical problem in foals that were 7 months old or older at the time of surgery, even though subluxation was evident radiographically and at necropsy.

Therefore, engagement of the caudal cortex of the radius should be avoided in foals younger than 1 year of age. If not, careful monitoring is necessary, and either the implants or the screws engaging the radius should be removed as soon as the fracture has healed (although subluxation can occur even after the implants are removed). If subluxation occurs, it can be managed with an osteotomy of the body of the ulna at a level distal to the joint (Fig. 97-5). By not fixing the osteotomy, the ulna can adjust into a normal position during the postoperative period. Another alternative is active proximal displacement of the proximal fragment through flexion and extension of the joint and subsequent bridging of the osteotomy gap with a narrow plate.

The proximal location of types 1 and 3 fractures challenges the fixation, because the small size of the proximal fragment limits the number of screws available for purchase. With a type 1b fracture, the plate is contoured over the dorsal aspect of the apophysis to allow purchase with three short screws. The fourth and usually the fifth screw in the plate are placed in lag fashion across the metaphyseal portion of the fracture to engage the cranial cortex of the olecranon (Fig. 97-6). Purchase in the cranial cortex of the olecranon adds substantial stability to the fixation.

Compression at the fracture line improves fracture reduction; this is particularly important for type 1b fractures that enter the articulation. Care is taken with type 1b fractures to avoid overcompressing the caudal aspect of the fracture using a DCP, because the cranial aspect of the fracture can become displaced. In these fractures, the initial screw is placed in the apophysis through the second plate hole, and another screw is placed in the sixth or seventh hole of the plate. These screws are not completely tightened, allowing the fracture to be held in reduction while the lag screws are placed across the metaphyseal fracture. Once the lag screws are tight, the remainder of the fixation is routine.

Prognosis

The prognosis following plate fixation of ulnar fractures is favorable. Success, defined as fracture union, occurred in 13 of 19 patients (68%), with a return to full function in 11 of the 13 cases. Another study reported return to full function in 16 of 21 patients (76%). Type 2 was the most common fracture configuration in both studies. When both patient populations were combined, full function returned in 27 of 34 patients (79%). Type 4 fractures were the second most common configuration, but only two of seven patients returned to full function. In 17 adult horses with comminuted articular fractures (type 4), long-term follow-up was available for eight, and five were sound enough for riding or training.

In a more recent retrospective study of 77 olecranon fractures, type 1b fractures were the most common configuration in young horses. Twenty horses underwent plate fixation as previously described (see Fig. 97-6). Fracture healing occurred in 19 of the 20 repaired fractures. Sixteen horses were available for long-term follow-up, and 13 (81%) were reported to be sound. Twelve horses were older than 2 years of age at the time of follow-up, and nine of these were performing their intended purpose. The remaining four horses, which were not yet 2 years of age, were all reported to be in training for their intended use without evidence of complications related to their fracture. In this case series there were no catastrophic fixation failures, and other complications were minimal. Furthermore, four horses with comminution at the anconeal process did not appear to be negatively affected by removal of the anconeal process fragment.

Tension-band wire fixation has been used to manage olecranon fractures in horses. In 22 horses managed with tension-band wiring, fracture union was achieved in 18 cases, and 13 of 17 horses returned to athletic function. Patients are candidates for tension-band wiring if they weigh 250 kg or less. When fractures are in close proximity to the physis, either pins or screws are positioned cranial to the apophysis and directed distally into the ulnar body. Distal fractures are repaired with wires alone or in conjunction with lag screws. Fractures in foals and weanlings are repaired with at least two or three 1.2-mm diameter wires, whereas four to six 1.5-mm diameter wires are used in older horses.

The advantages of tension-band wiring compared to plate fixation are less-expensive equipment, less risk of screws entering the joint space or engaging the caudal cortex of the MUSCULOSKELETAL SYSTEM
Figure 97-5. **A**, Follow-up radiograph of a mid-diaphyseal radius fracture in a foal treated with bone plates. The fracture shows progressive healing; however, there is a subluxation of the elbow joint. **B**, An ulnar osteotomy was performed 10 days prior to taking this radiograph, which resulted in correction of the subluxation and restoration of the normal joint anatomy. An osteotomy gap of 10 mm developed. **C**, The 6-year follow-up of the same animal shows a normal configuration of the joint without arthrosis and a sound animal. (Courtesy G. Bodo, Budapest.)
radius, less risk of fracture of the apophysis because screw holes in the proximal fragment are not necessary for fixation, and, with more distal fractures, less tissue dissection required.

Complications
Complications of repair of ulnar fractures are infection, fixation failure, tendon contracture, support limb varus deformity, suspensory apparatus fatigue, and support limb laminitis. Infection is most likely following repair of open, contaminated fractures. However, fractures with substantial soft tissue trauma also have an increased risk. Methods of reducing the infection potential include the use of perioperative systemic antimicrobial agents and, in high-risk patients, local application of antimicrobial-impregnated PMMA, usually as beads or in some cases as plate-luting material. If the fracture becomes infected, but the fixation is stable, a successful outcome is likely. However, the convalescent period is substantially prolonged, and lameness often persists until the infection is resolved. Resolution of infection requires implant removal once the fracture has healed. Infection in the presence of instability at the fracture invariably results in failure. Articular fractures that become infected have the additional risk of joint sepsis, which substantially worsens the prognosis.

Fixation failure can occur secondary to fracture of the apophysis in proximal olecranon fractures, especially with type 1a fractures in neonates, in which the apophysis is primarily cartilaginous. Following plate fixation of proximal fractures in older foals and adults, failure can result from fracture of the proximal fragment through the screw holes. However, this complication did not occur following plate fixation of 20 patients with type 1b fractures. Implant failure also can occur from using wire techniques, especially in large foals and adults. Therefore, fractures in large foals and especially in adults deemed at risk for implant failure are candidates for fixation using a broad DCP. Prolonged lameness for any reason results in a number of compensatory complications. Persistent lameness or increasing lameness in the postoperative period indicates fracture instability, infection, or both. With articular fractures, osteoarthritis secondary to incongruent joint surfaces or prolonged, severe synovitis causes persistent lameness. In foals, persistent lameness often results in varus deformities of both the carpus and the fetlock, as well as fatigue of the suspensory apparatus with hyperextension of the fetlock in the contralateral limb. The ipsilateral limb can develop flexural deformity of the carpus or fetlock, or both. In adults, ipsilateral flexor contracture may develop, but support limb laminitis is the most likely and potentially devastating complication.

FRACTURES OF THE RADIUS
In horses, radial fractures are not as common as ulnar fractures. When they occur, a wide variety of fracture configurations is possible. With most configurations, open reduction and internal fixation can be expected to produce a good to excellent outcome in horses weighing less than 250 kg. Fixation of radial fractures in adult horses, however, poses a substantial challenge. Although success has been reported, the prognosis for an adult horse with a completely displaced radial fracture is unfavorable.

Anatomy
The radius is the major weight-supporting bone of the antebrachium. Proximally, it articulates with the humerus, and with the ulna it forms the cubital joint. Distally, along with the proximal row of carpal bones, it forms the antebrachiocarpal joint. Proximally, the biceps brachii inserts on its cranial surface, and distally, the tendons of the digital extensor muscles pass through their respective tendon sheaths as they traverse the carpus en route to the digit. Medially, the radius lacks overlying muscle and is covered only by skin and subcutaneous fascia. The bone is strongly curved in the sagittal plane and has a distinct cranial bow. Biomechanically, this places the caudal cortex under substantial compression. The cranial and cranialateral aspects of the radius are loaded in tension.

In foals, a proximal and a distal physis are present. These physes, along with their respective epiphyses, are subjected to compressive forces. Therefore, fractures involving these physes are classified according to the Salter-Harris scheme. Growth at these physes is responsible for the ultimate length of the bone and thereby affects limb length and conformation. Disproportionate growth at the distal radial physis is a common cause of carpus valgus limb deformity.

Pathogenesis
Most radial fractures result from external trauma. In foals, entrapment of the limb proximal to the carpus can result in proximal radial physeal fractures. However, direct blows to
the antebrachium are the most common cause of fracture in both foals and adults. Often, the cause of the fracture is a kick from another horse.

Commonly, the fracture is comminuted, regardless of the patient’s age. In adults, comminution almost always accompanies either a spiral or an oblique fracture of the diaphysis. The degree of comminution varies from single or multiple large butterfly fragments to multiple small fragments. Incomplete or complete nondisplaced fractures of the radius often occur in adult horses that have been kicked. Often these injuries are witnessed as a solid blow to the distal medial aspect of the antebrachium. A skin wound may be evident.

Because the fracture is not displaced and instability is not readily apparent, radiographs are occasionally omitted from the evaluation. Because the horse remains noticeably lame, the fracture is detected later; when it becomes unstable or radiographs are taken because the lameness fails to resolve. Therefore, radiographic examination is recommended in all cases in which there is evidence of a kick injury to the antebrachium.

Occasionally, if the initial radiographs are taken immediately after the incident, the fracture cannot be detected. Follow-up radiographs taken 5 to 7 days after the injury allows identification of the fracture lines.

The degree of fragmentation accompanying comminuted fractures in foals is less than that of comminuted fractures in adults. Fracture configurations in foals vary. Mid-diaphyseal transverse fractures result from a cranial blow to the antebrachium. A lateral blow results in an oblique fracture of the proximal metaphysis. Physeal fractures occur at both the proximal and the distal radial physes. Displacement with Salter-Harris type I and type II fractures of the proximal physis is accompanied by fracture of the ulna. If the radial metaphysis displaces cranially, injury to the radial nerve is possible. Salter-Harris type III fractures are encountered most commonly in the proximal epiphysis.

Diaphyseal fractures of the radius are at high risk of becoming open secondary to skin penetration by the sharp fracture fragments on the medial aspect of the antebrachium. Abduction of the distal limb displaces the fracture into the relatively thin soft tissues medially, and the fracture often becomes open. In addition, there is often substantial injury to the musculature covering the dorsal and lateral aspects of the antebrachium, accompanied by severe soft tissue swelling and hematoma. The degree of soft tissue injury accompanying radial fractures makes them highly susceptible to infection at the fracture site.

**Diagnosis**

Complete displaced radial fractures are easily identified on physical examination. Non–weight-bearing lameness accompanied by instability and crepitation in the antebrachial region is pathognomonic for these injuries. The patient usually holds the limb with the carpus and fetlock flexed and drags the toe. Attempts at weightbearing result in valgus angulation at the fracture. Soft tissue swelling is usually evident. Wounds or secondary penetration of the medial soft tissues are often present. Horses with incomplete fractures or with nondisplaced complete fractures do not demonstrate instability or crepitation. However, they are usually lame, and in many cases a wound is evident at the site of traumatic impact.

Radiographic evaluation confirms the presence of a fracture. Multiple views, including oblique projections, are advisable to delineate the severity of the fracture and to assist in determining a course of action and rendering a prognosis. It is important to delineate the extent and location of fragmentation in comminuted, completely displaced fractures. Nondisplaced fracture lines usually emanate proximal and distal from the displaced fracture. Occasionally, these are evident only after the fracture is surgically exposed, but complete radiographic evaluation before attempting internal fixation determines the feasibility of repair and the best method for managing the fracture.

Fractures with multiple small fragments that are likely to preclude anatomic reconstruction should be identified. This is especially important when these fragments are located along the caudal cortex, which must be reconstructed for repair to be successful.

**Treatment**

**First Aid**

As with ulnar fractures, wounds associated with a displaced fracture of the radius require immediate attention. There is a high probability that wounds at the medial aspect of the antebrachium communicate directly with the fracture. Initial management should include appropriate hair removal, cleansing, and topical and systemic antimicrobial therapy.

Immediate immobilization of a displaced fracture is paramount. With closed fractures, appropriate external coaptation can prevent fragments from displacing and the fracture from opening. Sedation is necessary for applying a bandage and splint with an unstable radius fracture. Once the patient is controlled, and after appropriate wound therapy in open fractures, a Robert Jones bandage is applied extending from the hoof to as far proximal on the antebrachium as possible.

The bandage should be applied in layers to increase rigidity. A caudal splint is applied that extends from the ground to the level of the olecranon process. A second lateral splint extends from the ground to the level of the mid-scapula. The portion of the splint extending proximal to the bandage should contact the brachium when the limb is directly beneath the body (Fig. 97-7). This provides counter-pressure to prevent the limb from abduction with weight-bearing. Nonelastic adhesive tape or fiberglass casting tape is used to affix the splints to the bandage. More information on bandaging and first aid for fracture patients can be found in Chapters 18 and 78.

**Nonsurgical Management**

Incomplete and nondisplaced complete fractures are candidates for conservative therapy.\(^1\) Predicting success based on the radiographic appearance of the fracture was not possible. An important aspect of therapy was preventing recumbency to reduce the
likelihood of displacement secondary to forces experienced during standing up (see Fig. 81-1).

Phenylbutazone should be used judiciously to reduce inflammation and encourage limited weightbearing on the fractured limb. Care should be taken to avoid providing substantial pain relief, which could result in overuse of the fractured limb.

The horse is confined until there is evidence of advanced fracture healing. This usually requires a minimum of 3 to 4 months. During the last 30 days of confinement, a program of gradually increasing hand-walking is recommended. Access to free paddock exercise is allowed thereafter. An additional 30 days of paddock exercise is recommended before the horse is gradually returned to its intended function.

Surgical Management

ADULT HORSES

Open reduction and internal fixation of displaced radial fractures in adult horses is a monumental task that provides only a limited chance of survival. In many cases, the fracture configuration and degree of soft tissue trauma preclude any reasonable likelihood of success. Even with fractures amenable to fixation, the biomechanical forces acting on the bone–implant construct place the fixation at risk for failure. Even the strongest, most stable construct has a high potential either to fail catastrophically during recovery or to fatigue and fail before fracture union.

Fixation with two plates is necessary; one plate is positioned cranially and the second plate is applied to either the medial or the lateral cortex. One of the plates should be a dynamic condylar plate, with the condylar screw placed in the smaller fracture segment. The second plate should be a broad 5.5-mm LC-DCP or DCP. As many 5.5-mm cortex screws as possible are implanted, and every opportunity to provide compression across fracture lines is used (Fig. 97-9). The entire length of the radius is spanned by the plates, and the plates should be offset to avoid ending at the same level in the transverse plane. Plate luting with antimicrobial-impregnated PMMA is recommended even though the PMMA loses some strength from the solvent that is added for the antibiotic. Cancellous bone grafts should be incorporated into the fixation to promote healing.

FOALS

Diaphyseal fractures in foals, other than simple transverse mid-diaphyseal fractures, are double plated as well. Implant selection depends upon the size of the foal, the fracture configuration, and the location. A broad LC-DCP or DCP is usually applied to the cranial cortex, and in most cases, 5.5-mm cortex screws are used throughout its length. The second plate may be either a broad or narrow LC-DCP or DCP fixed with a majority of 4.5-mm cortex screws. However, nearest the fracture and at the ends of the plate, 5.5-mm cortex screws should be inserted. With proximal oblique fractures, the second plate is placed lateral distally and twisted proximally to end on the craniolateral aspect of the proximal metaphysis, lateral to the insertion of the biceps brachii tendon on the radial tuberosity (Fig. 97-10).

Comminuted fractures

In foals with comminuted fractures, the repair is as described for adults, with the exception of implant selection. A second broad LC-DCP or DCP is used in place of the dynamic condylar screw plate. The author prefers to place the second plate laterally, unless the configuration of the fracture dictates medial placement. Lateral placement, although technically more demanding, avoids positioning...
the implant subcutaneously and, particularly in fractures that are open medially, avoids direct communication with the wound. In most cases, both implants can be placed using a lateral approach between the extensor carpi radialis and common digital extensor muscles. If the lateral plate is extended to the distal end of the radius, placement of the distal screws might require separate stab incisions lateral to the common digital extensor tendon.

Mid-diaphyseal fractures
Mid-diaphyseal transverse fractures are repaired with a single broad LC-DCP or DCP applied to the cranial cortex, provided the caudal cortex can be anatomically reconstructed. The strong cranial-to-caudal bending moment of the radius makes this a stable fixation in foals weighing less than 250 kg. With single-plate fixation, it is advisable to use 5.5-mm cortex screws throughout the entire length of the plate.

Proximal physeal fractures
Fractures at the proximal physis are less common than diaphyseal or metaphyseal fractures. They are candidates for internal fixation, with special considerations.

Type III fractures are uncommon, and conservative therapy is successful in nondisplaced fractures. However, anatomic reconstruction of the articular surface and compression across the fracture is the treatment of choice for displaced fractures. This is accomplished with lag screw fixation alone or in combination with tension band wire fixation.

Salter-Harris types I and II fractures of the proximal physis are accompanied by fracture of the ulna (Fig. 97-11, A). Plate fixation of the ulnar fracture, with screws engaging both cortices of the radius where possible, combined with a laterally applied narrow DCP with the most proximal screw in the radial epiphysis, is recommended (see Fig. 97-11, B). With small foals, transphyseal screw and wire fixation in place of the plate on the lateral aspect of the radius can be used.

Transfixion of the ulna and radius can result in elbow subluxation, but growth at the physis is minimal because of injury of the germinal layers of the growth plate and because the implants bridging the physis restrain growth. Because physeal growth is minimal, the ulna does not displace relative to the radius as the foal matures. The apparent disparity in bone length between limbs does not have an adverse effect on gait.

If the metaphyseal portion of the fracture displaces cranially (Fig. 97-12), the radial nerve can be traumatized, resulting in low radial nerve paresis. Difficulty in active extension of the digit occurs. Most foals learn to place the foot on the ground appropriately, and the paresis usually resolves.

Distal physeal fractures
Fractures of the distal physis are less common than fractures of the proximal physis. Salter-Harris type I physeal fractures result in displacement at the medial aspect of the physis (Fig. 97-13, A). The fractures occur in neonates and are
Figure 97-11. Craniocaudal radiograph of a Salter-Harris type II fracture of the proximal radius prior to repair (A) and after the application of a narrow dynamic compression plate (DCP) to the lateral aspect of the proximal radius and a second narrow DCP applied to the ulna with screws transfixing the ulna to the radius (B).

Figure 97-12. Lateromedial radiograph of Salter-Harris type II fracture of the proximal radius and ulnar fracture with cranial displacement of the distal fragment, resulting in temporary radial nerve paresis.

treated by transphyseal bridging across the medial aspect of the physis. A T-plate or screws and wires can be used (Fig. 97-13, B). When the fractures are healed, the implants are removed.

**Prognosis**

Adults with displaced radial fractures have an unfavorable prognosis. In rare instances, successful internal fixation can be achieved. In one report, internal fixation was attempted in six adult horses, none of which survived. In another case series, nine of 15 horses that were presented for radial fracture had attempted internal fixation, and only two were discharged from the hospital. However, with careful case selection and improved methods of increasing the strength and stability of the bone–implant construct, the success rate can be improved. The substantial expense associated with fixation, combined with the high risk of failure, often dissuades owners from pursuing repair.

Displaced radial fractures in foals, however, particularly if there is no comminution and when the fracture is closed, have a favorable prognosis. Physeal fractures and transverse fractures of the mid-diaphysis have an excellent prognosis. In six of seven foals with mid-diaphyseal transverse fractures, and in two foals, one with Salter-Harris type I and another with a type II proximal physeal fracture, the fractures healed. Similarly, fixation of proximal oblique fractures in three of four foals had an excellent outcome.

**Complications**

Complications following repair of radial fractures are the same as for any equine long bone fracture repair. Infection, instability, failure of fixation, and support limb complications are the most common. The propensity for radial fractures to be open medially substantially increases the risk of infection. Even in closed fractures, the degree of soft tissue trauma and the lack of muscle covering of the medial aspect of the radius increase the potential for infection. The technical difficulty of the repair often prolongs surgery time. The quantity of implants used for repair significantly contributes to postoperative infection.

Fixation failure is the most common fatal complication. Catastrophic failure is a major risk during recovery from anesthesia, particularly in adult horses. Long surgery time and the condition of the patient at the time of anesthesia play major roles. Attention to the patient’s physiologic status before and during anesthesia, along with a controlled recovery, can reduce the incidence of failure. The technical difficulty of the fixation dictates that an experienced surgical team be assembled. Every effort is made to minimize surgery time.

Fatigue failure of the implants is not uncommon. This is especially a problem in adults, where the high loads experienced by the bone–implant construct cause micromotion and cycle the implants. The greater the instability, the greater the probability of fatigue failure. Bone-to-bone contact is imperative at the caudal cortex. If that is not achieved, cyclic loading fatigue failure is inevitable (Fig. 97-14). Methods to reduce the likelihood of fatigue failure include using the strongest implants available and plate luting. Anatomic reconstruction of the fracture, especially at the caudal cortex, is an absolute necessity.

To prevent support limb complications, an early return to weightbearing on the fractured limb is best accomplished by restoring stability to the fracture site and preventing infection. In foals, the primary concern is for varus limb deformity and fatigue of the suspensory apparatus resulting in fetlock hyperextension. To reduce these complications, a foot plate with an extended heel and lateral bearing surface is applied. Support bandages are not advocated in foals because they tend to promote fetlock hyperextension rather than prevent it. In adults, to preclude support limb laminitis, appropriate footing is helpful. In addition, heart bar shoes are used, which reduce the frequency of support limb laminitis. Support wraps and judicious use of phenylbutazone are recommended in adults during the postoperative period.

**OSTEOCHONDROMA**

Osteochondromas originate from the dysplastic growth of aberrant growth cartilage. They are located adjacent to a physis and occur most commonly in adult horses at the caudal aspect of the distal radius. Solitary osteochondromas have been reported in two foals; in one the calcaneus was affected, and in the other the distal palmar aspect of the middle phalanx was affected. Osteochondromas are exostoses composed of trabecular bone contiguous with cancellous bone of the adjacent medullary cavity. There is a characteristic cartilage cap composed of hyaline cartilage undergoing endochondral ossification. The histologic characteristics are identical to those of multiple cartilaginous exostoses of horses. However, the genesis of the lesion in the latter condition is hereditary. To date, a hereditary basis for solitary osteochondroma has not been identified.

**Pathogenesis**

Causes of solitary osteochondroma include displacement of a growth cartilage fragment that rotates and grows transverse to the longitudinal axis of the bone, aberrant nest of subperiosteal growth cartilage, and herniation of growth cartilage through a perichondral defect. With continued growth, the expansile nature of the lesion impinges on adjacent structures and results in lameness. Osteochondromas of the caudal distal radial physis are located in the carpal canal and cause tenosynovitis. They also impinge on the deep digital flexor tendon as it passes through the area. Bony projections that are not true osteochondromas, referred to as physeal remnant spikes, have been noted to cause the same clinical syndrome (see Chapter 96).

**Diagnosis**

Horses with distal radial osteochondromas or physeal spikes are presented with effusion in the carpal canal. Lameness is mild and intermittent. Pain is evident on direct palpation and is induced by carpal flexion. In some cases, the bony projection can be identified by deep palpation. Radiography reveals the characteristic bone growth on the palmar aspect of the physis. A T-plate or screws and wires can be used (Fig. 97-13, B). When the fractures are healed, the implants are removed.
of the radius adjacent to the physis (Fig. 97-15). There is a wide variation in the size and degree of ossification of the lesion. Ultrasonography can aid in determining the presence of deep digital flexor tendinitis. However, the absence of ultrasonographic changes does not preclude the presence of superficial injury to the tendon due to impingement by the osteochondroma or physeal spike.

**Treatment**

Instillation of corticosteroids into the tendon sheath temporarily resolves tenosynovitis in most instances. However, clinical signs usually recur. Surgical excision of the bony projection is curative and is the treatment of choice. Although excision via an open approach to the lateral aspect of the carpal canal was originally reported, removal under arthroscopic guidance is currently advocated.

With the affected limb positioned uppermost, the arthroscope is placed into the proximal aspect of the carpal canal through a stab incision located 3.5 cm proximal to the level of the physeal scar between the lateral digital extensor and ulnaris lateralis muscles. Although a medial approach has been described, the surgeon is less likely to injure the median artery and vein from a lateral approach. Furthermore, the lateral approach makes it technically easier to manipulate the scope and instruments without interference from the opposite limb.

Once the arthroscope is in the carpal canal, the sheath is distended and the osteochondroma or physeal spike is readily identified (Fig. 97-16). The bony projection’s attachment to the underlying bone is severed with a small osteotome positioned through a separate stab incision distal to the scope portal, and the bony projection is removed. Release of the carpal flexor retinaculum can also be accomplished via endoscopic guidance if chronic distention of the carpal canal is diagnosed as a complicating problem. The bone bed is curetted and the sheath is lavaged before closure of the skin incisions. Postoperative care is routine.
Prognosis

Horses are reported by their owners to be sound for their intended purpose following removal of the osteochondroma or physeal spike.\textsuperscript{17-19,22,23} Distention of the carpal canal resolves. With chronic carpal canal distention, resolution of the effusion following osteochondroma removal can require additional medical therapy, including local corticosteroid injection.

\textbf{REFERENCES}

Orthopedic abnormalities of the scapulohumeral (shoulder) joint are rare. Because shoulder pathologies are uncommon and relatively difficult to diagnose, treatment can be delayed, leading to an increase in secondary osteoarthritis. Further, there are very few large studies documenting treatment and outcome following specific injuries or treatments to guide the surgeon.

**DIAGNOSIS OF SHOULDER LAMENESS**

Localization of lameness to the shoulder region can be straightforward in cases where there is associated swelling or pain on palpation, but in many cases intra-articular or bursal anesthesia is necessary to confirm clinical examination findings. Horses with fractures of the shoulder region or luxation of the scapulohumeral joint are acutely, and initially, severely lame and have localized swelling. When the scapulohumeral joint is less severely affected, joint effusion cannot be palpated because of the overlying musculature, but a painful response can often be elicited following deep palpation of the notch between the cranial and caudal prominences of the greater tubercle of the humerus. Horses with biceps tendinitis or intertubercular bursitis (bicipital bursitis) often exhibit moderate pain when the biceps tendon or muscle is grasped and palpated. Less-specific signs of shoulder lameness include shoulder muscle atrophy, pain on extension or flexion of the shoulder joint, a narrow ipsilateral hoof with a long heel, and, typical of forelimb lameness, signs of a shortened anterior phase of the stride. Nuclear scintigraphy can help localize the cause of a subtle lameness to the shoulder joint.

When the lameness is localized to the shoulder region, radiographs should be obtained. If bicipital bursitis or biceps tendinitis is suspected, an ultrasonographic examination should be performed. Although not currently available for imaging equine shoulders, magnetic resonance imaging (MRI) is considered the method of choice for evaluation of shoulder pain in people because it provides detailed information on all bone and soft-tissue components of the shoulder.

Radiographs of the shoulder joint usually can be obtained in the standing horse, although higher-quality images are achieved when the horse is under general anesthesia because of the absence of motion artifact. The horse’s leg is extended forward to center the shoulder joint over the trachea for a mediolateral projection. Normal survey radiographs do not exclude the shoulder as a cause of lameness, particularly in cases of osteochondrosis (OC) or other cartilaginous pathologies of the humeral head or glenoid cavity. In cases where survey radiographs are normal and OC is suspected, positive-contrast radiography using 7 to 10 mL of a sterile water-soluble iodinated contrast medium should be performed. Double-contrast radiography more clearly delineates the glenoid notch than positive-contrast radiography. To obtain a double-contrast image, 30 mL of air is injected following positive-contrast radiography.

**INTRASYNOVIAL ANESTHESIA OR SYNOVIAL CENTESIS**

When clinical examination findings do not definitively localize the lameness to the shoulder joint or bicipital bursa, diagnostic intrasynovial anesthesia can be useful. Local anesthetic (20 mL) is delivered into the shoulder joint using an 18-gauge, 8.9-cm spinal needle inserted in the notch between the cranial and caudal prominences of the greater tubercle of the humerus. The needle is directed toward the elbow of the opposite limb, parallel to the ground, and is advanced until bone or cartilage is contacted. Extrasynovial deposition or leakage of local anesthetic solution out of the shoulder joint can block the suprascapular nerve, resulting in lateral subluxation of the scapulohumeral joint, thereby producing the clinical appearance of sweeney. If the suprascapular nerve is inadvertently blocked, the horse should be placed in a box stall until the anesthetic wears off to prevent injury. In horses with intact cartilage that covers subchondral bone abnormalities, there might be minimal or no improvement in lameness following intra-articular anesthesia.

The bicipital bursa is entered approximately 4 cm proximal to the distal aspect of the deltoid tuberosity. An 18-gauge, 8.9-cm spinal needle is inserted between the biceps brachii muscle and the humerus and directed proximomedial to approximately 4 cm in depth, where 5 to 10 mL of local anesthetic is injected. Synovial fluid can usually be aspirated from both the shoulder joint and bicipital bursa to confirm intrasynovial needle placement and therefore deposition of local anesthetic or for synovial fluid analysis and culture in cases where infection is suspected.

**OSTEOCHONDROSIS**

Osteochondrosis (OC) occurs in the shoulder joint less often than in other sites such as the tarsocrural or femoropatellar joint. Clinical signs usually appear in horses 6 to 12 months old, and the lesions can be bilateral. Clinical examination in combination with conventional or contrast radiography reveals that the majority of shoulder OC lesions in horses are osteochondritis dissecans (OCD) lesions (cartilage flaps). Typical radiographic signs include irregular areas of subchondral bone with radiolucent areas surrounded by sclerosis. Contrast radiography more clearly delineates the presence and extent of undermined cartilage flaps and aids in determining a more accurate preoperative prognosis than one based on plain radiographs alone (Fig. 98-1). Subtle cartilage lesions might not be detected using current imaging modalities, and diagnostic arthroscopy should be used if clinical examination, intra-articular anesthesia, or nuclear scintigraphy implicates the shoulder joint as the source of lameness.

Secondary osteoarthritis (OA) develops rapidly in cases of shoulder OCD, and radiographs should be carefully scruti-
nized preoperatively for signs of OA, because the prognosis for future athletic function is poor in affected horses. Radiographic signs of shoulder OA include flattening of the humeral head and glenoid cavity, remodeling of the caudal rim of the glenoid, and subchondral bone sclerosis of the humeral head or glenoid cavity.3

Treatment
Arthroscopic surgery with débridement of loose cartilage flaps and curettage of abnormal underlying subchondral bone is the treatment of choice for shoulder OCD lesions. Repair of cartilage flaps using polydioxanone pins has been successful in select cases of OCD involving the femoropatellar and metacarpophalangeal joints and should be considered for cases of shoulder OCD.6 Only cases with smooth, partially attached, unmineralized cartilage flaps should be considered for repair with polydioxanone pins.

Arthroscopy of the shoulder joint is technically more challenging than other joints. Lateral and craniolateral approaches have been reported.7,9 The lateral approach is described here because it provides maximal visualization of the medial aspect of the humeral head and leaves the cranial portal (cranial to the infraspinatus tendon and proximal to the notch between the cranial and caudal prominences of the greater tubercle of the humerus) open for insertion of an egress cannula. The open cranial portal can also be used to introduce a large curved forceps, which can be engaged in the glenoid notch to distract the humeral head and gain access with the arthroscope to the medial side of the joint.

To perform shoulder arthroscopy, the horse is placed in lateral recumbency with the affected limb uppermost. The leg should be draped to allow adduction and traction during surgery in order to increase surgical exposure. The joint is distended with 60 mL lactated Ringer’s solution using an 18-gauge, 8.9-cm spinal needle inserted in the notch between the cranial and caudal prominences of the greater tubercle of the humerus (this site becomes the cranial portal). The arthroscope is inserted 1 to 2 cm caudal to the infraspinatus tendon and cranial to the teres minor muscles. A third site 2 to 4 cm caudal to the arthroscope portal can be used as an instrument portal. The optimal site for instrument portal entry is determined using an 18-gauge, 8.9-cm spinal needle. If the lesions are extensive, or if they occur on the humeral head and glenoid cavity, more than one instrument portal might be required to complete the surgical débridement.

Cartilage flaps are removed and subchondral bone is débrided using several instruments including Ferris-Smith rongeurs, motorized resectors, periosteal elevators, and curets (Fig. 98-2). Lesions on the most medial aspect of the humeral head might be inaccessible. When débridement is complete, the joint is lavaged to remove cartilage and bone debris and the skin incisions are closed routinely.

Antibiotics and phenylbutazone are administered perioperatively, and phenylbutazone is continued for the next 5 to 10 days. Horses are restricted to stall rest for 14 days, at which time hand-walking begins for 5 minutes per day. After 30 days of stall rest with hand-walking, horses are turned out for 4 to 6 months before exercise is resumed.

Prognosis
The prognosis for return to soundness depends on the severity of the lesion and the presence of concomitant OA. The prognosis is poor when OA is detected on preoperative radiographs or when lesions are present on both the humeral head and opposing glenoid cavity. Typically, lesions identified during arthroscopy are more extensive than suggested by radiography.4,7 The prognosis is fair to poor in horses with bilateral lesions, regardless of lesion size. However, in
cases where more subtle lesions are present, the prognosis for return to athletic function is good, even for middle-aged horses.4

FRACTURE OF THE SUPRAGLENOID TUBERCLE
Supraglenoid tubercle fractures are usually simple, intra-articular epiphyseal fractures. These fractures occur most commonly in horses younger than 2 years of age and are either the result of direct trauma or are avulsion fractures caused by tension from the biceps tendon, which originates on the supraglenoid tubercle. Horses with supraglenoid tubercle fractures are able to bear weight, but they are variably lame and reluctant to fully extend the affected limb.

Careful visual inspection and palpation of the cranial aspect of the shoulder will be suggestive of a supraglenoid tubercle fracture. In chronic cases, shoulder muscle atrophy will be present. Radiography of the shoulder is diagnostic. On a mediolateral projection, the fracture fragment is typically displaced in a cranioventral direction as a result of tension from the biceps brachii and coracobrachialis muscles, which originate on the supraglenoid tubercle (Fig. 98-3). The radiographs should be carefully evaluated for signs of OA (described previously), which will decrease the prognosis for athletic function.

Treatment
Several treatment options are available, and the therapy chosen will depend on the duration of the fracture and the intended use of the horse. Conservative management for all but the smallest fractures typically results in residual lameness and OA of the shoulder joint. Surgical options include repair of the fracture or removal of the fracture fragment. The goal of surgical repair should focus on restoring articular congruity of the glenoid cavity to prevent the development of OA. Therefore, if the fracture is chronic (longer than 1 week), enough bone remodeling will have occurred to preclude accurate reduction of the fracture, and the fragment should be removed. In acute fractures, if a substantial (one third or greater) portion of the glenoid cavity is involved, internal fixation should be considered to reconstruct the glenoid articular surface and provide maximal opportunity for future athletic performance. Acute cases where more subtle lesions are present, the prognosis for return to athletic function is good, even for middle-aged horses.4
Fracture fragments that involve only a small portion of the glenoid cavity can be removed with no apparent impact on future athletic performance.

**Fracture Fragment Removal**

The horse is placed in lateral recumbency with the affected limb uppermost. A 20-cm skin incision is made, beginning at the distal extent of the scapular spine, centering over the cranial aspect of the point of the shoulder, and extending distally over the deltoid tuberosity. The brachiocephalicus and supraspinatus muscles are separated and retracted; the brachiocephalicus is retracted caudally and the supraspinatus cranially.

At this point, repeated palpation will guide the surgeon to the shoulder joint and fracture fragment. Care should be taken to identify and preserve the suprascapular nerve, artery, and vein as they course across the neck of the scapula. The articular surface of the humeral head and glenoid cavity should be inspected for signs of cartilage damage, which will diminish the prognosis for athletic function. The fracture fragment is grasped with a large bone-holding forceps and excised using a combination of blunt and sharp dissection to detach the muscular and tendinous attachments. The dissection can be challenging, particularly on the medial aspect of the fragment because of lack of visualization.

Following removal of the fragment, the area is lavaged and closed in several layers to diminish dead space. If substantial dead space remains, a closed suction device should be used to prevent development of a postoperative seroma. Assisted recovery from anesthesia is recommended. Antibiotics and phenylbutazone are administered perioperatively and continued until there are no clinical signs of seroma formation.

Horses are restricted to stall rest for 60 days to allow time for the dead space to fill with fibrous tissue and the biceps to reattach. A carefully controlled rehabilitation program is important for these horses to regain strength and coordination in their shoulder joints. Percutaneous stimulation of the shoulder muscles during rehabilitation to minimize muscle atrophy should be considered. In humans, percutaneous muscle stimulation has been shown to minimize muscle atrophy after stroke or spinal cord injury. Typically, physical therapy begins with range-of-motion exercises and hand-walking for 5 minutes per day, followed by walking over ground poles and gradual increases in duration of exercise each day. Horses are not usually ready to return to training or to be turned out into a paddock for 6 to 12 months after surgery.

**Fracture Fixation**

A variety of techniques have been described for internal fixation of supraglenoid tubercle fractures. Tension from the biceps tendon is the primary force that needs to be neutralized when performing internal fixation. Partial or full transection of the biceps tendon to prevent tension on the fracture repair and facilitate internal fixation has been described, but it is not routinely recommended.

The fracture site is approached as described previously for fragment removal. The fractured bone ends are débrided and the fracture is reduced using large bone-reduction forceps. The fracture is repaired using two or three 5.5-mm cortical bone screws placed in lag fashion. Care is taken to implant the screws in a somewhat diverging pattern to increase resistance to the axial tension on the implants. Additional support is provided by tension band wiring between the supraglenoid tubercle and the cranial edge of the scapula using large-diameter (1.5-mm) wire (Fig. 98-4). Wound closure and immediate postoperative care are similar to that described for fracture fragment removal.

Following internal fixation, horses are confined to a box stall for at least 8 weeks, until postoperative radiographs indicate sufficient fracture healing. An intense rehabilitation program involving physical therapy and a controlled exercise protocol should be prescribed until shoulder musculature returns to normal, at which time training may be resumed.

**Prognosis**

Return to athletic function depends on the amount of cartilage damage present at the time of surgery and, in cases where the fracture fragment is removed, the amount of glenoid cavity removed with the fracture fragment. Both of these factors are assumed to be directly related to development of shoulder OA. The few reports that are available regarding supraglenoid tubercle fractures in the horse suggest that the prognosis for athletic function is fair following either fracture removal or internal fixation but poor with conservative treatment.

**MISCELLANEOUS OTHER FRACTURES**

Fractures of the neck or body of the scapula or proximal humerus are rare but have been described. These fractures are usually the result of trauma, and horses are variably lame.
The cranial and caudal aspects of the greater tubercle of the proximal humerus can fracture in different configurations. If the entire greater tubercle fractures transversely, the scapulohumeral joint can luxate. When clinical examination or nuclear scintigraphy suggests involvement of the greater tubercle, a skyline radiograph of the proximal humerus should be obtained to diagnose the fracture (Fig. 98-5). Depending on the size of the fracture fragment and the muscular attachments involved, the fragment may be treated conservatively, removed, or repaired using cortex or shaft screws placed in lag fashion.

Horses with complete fractures of the body of the scapula or scapular neck will be unable to bear weight. A standing mediolateral radiograph with the affected limb pulled forward will reveal the fracture site. If the neck of the scapula is involved, function of the suprascapular nerve should be evaluated (described later in “Suprascapular Nerve Injury”). Internal fixation of complete fractures of the scapula has been described using two plates, one on each side of the scapular spine.16,17 Incomplete fractures can be managed conservatively.18

**SCAPULOHUMERAL JOINT LUXATION**

Scapulohumeral joint luxations are rare in horses and are traumatic in origin. Because of their traumatic nature, concurrent fractures of the scapula or proximal humerus can occur.14 The horses are non-weight-bearing and might have shoulder atrophy if the luxation is chronic. The humeral head can be palpated lateral, or less commonly cranial, to the scapula. Standing cranio-caudal to mediolateral oblique-view radiographs best demonstrate the luxation (Fig. 98-6). The radiographs should be carefully evaluated for fractures.
of the humeral head or scapula, particularly involving the lateral rim of the glenoid.

Treatment

Closed reduction followed by scapulohumeral joint arthroscopy to evaluate the articular surfaces and remove cartilage debris resulted in return to sound performance in one case.20 Closed reduction should be attempted before an open approach is performed to preserve intact lateral musculature of the shoulder joint and minimize the potential for re-luxation of the shoulder joint postoperatively. Open reduction should be combined with some form of internal fixation such as scapulohumeral tension wires, although most types of internal fixation eventually fail.19

The ultimate outcome for most horses with scapulohumeral luxation is shoulder OA and severe lameness, resulting in euthanasia. Arthrodesis of the scapulohumeral joint has been successful in one small (250 kg) horse21 and in miniature horses.22,23 Arthrodesis is accomplished using a narrow dynamic compression plate contoured to the cranial surface of the scapula and cranial aspect of the humerus.23 For more information, review Chapter 85.

Prognosis

There are very few reports detailing repair of scapulohumeral joint luxation, but the prognosis for soundness following repair appears to be poor because of resultant crippling shoulder OA.

PATHOLOGIES OF THE INTERTUBERCULAR BURSA AND BICEPS BRACHII

The biceps brachii muscle originates on the supraglenoid tubercle as a bilobed, tendinous structure, and it inserts, again as a tendon, on the medial radial tuberosity. It passes over the proximal, cranial aspect of the humerus, where it is bound to the intertubercular groove by a tendinous part of the superficial pectoral muscle. The intertubercular (bicipital) bursa lies between the proximal biceps tendon and the humerus.24

Horses with bicipital bursitis or biceps tendinitis exhibit pain when the biceps is grasped and pulled laterally. Nuclear scintigraphy can be helpful in any of the vascular, soft tissue, or bone phases, but a definitive diagnosis requires intrasynovial anesthesia. After localizing the lameness to the biceps region, an ultrasonographic and radiographic examination of the biceps region should be obtained. Normal ultrasonographic morphology of the biceps tendon and bicipital bursa have been reported.25 Skyline radiographs of the proximal humerus are required to identify concurrent lesions involving the humeral tubercles (Fig. 98-7).

Various pathologies have been reported in association with the biceps tendon or bicipital bursa including bursitis,26-28 tendinitis,26 ossifying tendinitis,29 medial displacement of the biceps tendon,30 and infectious bursitis.31,32 Simple biceps tendinitis is managed conservatively, but surgical intervention should be considered for horses with idiopathic or infectious bursitis or with chronic bicipital bursitis.

Treatment

Endoscopy

Infection of the bicipital bursa should be addressed using endoscopy and systemic antimicrobials. Endoscopy permits a thorough exploration of the infected bursa as well as a means of copious lavage and removal of adhesions. Synovial resection should be considered; however, it is controversial in cases of septic arthritis.

Endoscopy of the bicipital bursa in normal and infected bursae has been described.31,32 The horse is positioned in lateral recumbency, with the affected limb uppermost. The bursa is distended with 100 mL lactated Ringer’s solution as described under “Intrasynovial Anesthesia.”

The arthroscope is inserted into the distal aspect of the bursa through a skin incision placed 2 to 3 cm proximal to the deltoid tuberosity on the dorsolateral aspect of the humerus. The arthroscope is advanced proximomedially through the brachiocephalicus muscle, beneath the biceps brachii muscle, and along the cranial surface of the humerus. When the distended bursa is entered, and fluid escapes from the cannula, the obturator is removed and replaced with the arthroscope. The instrument portal site is predetermined by placement of a spinal needle in the proximal aspect of the bursa, lateral to the biceps tendon. The bursa is explored and any foreign debris and adhesions are removed.

The type and duration of antibiotic and anti-inflammatory medications administered will depend on the presence or absence of sepsis. Similarly, postoperative rehabilitation and return to training or performance will be related to the degree of tendinitis or bursitis.

Biceps Tendon Transection

A combination of bicipital bursitis, biceps tendinitis, and humeral osteitis has been reported in horses.27,28 This disease complex is thought to be a manifestation of chronic bursitis or tendinitis and can be infectious or traumatic in origin. Affected horses are severely lame and unresponsive to conservative therapy. Ultrasonography of the biceps bursa is consistent with bursitis, and skyline radiographs of the proximal humerus reveal osteolytic changes associated with the lateral tuberosity.

Complete transection of the biceps tendon results in a fair prognosis for return to soundness.37 If purulent material is found within the biceps brachii tendon, then a tenectomy should be considered. The approach to the biceps tendon is the same as that described for removal of supraglenoid tubercle fractures. Postoperative management is also similar to that for removal of supraglenoid tubercle fractures because biceps tendon support is lost in both instances. There is, however, less dead space to be filled in by fibrous tissue.

Prognosis

There are too few reports of the various biceps tendon or bursa problems to provide an accurate prognosis. As with most synovial structures, the prognosis for return to sound function ranges from guarded to good depending on the structures involved and the duration of clinical signs.
The suprascapular nerve is typically damaged as the result of trauma to the cranial shoulder where the nerve courses across the neck of the scapula. The suprascapular nerve innervates the infraspinatus muscle, which provides the majority of lateral support to the shoulder. As a result, horses with suprascapular nerve injury have a lateral motion or shoulder slip during weightbearing on the affected limb.

If damage to the nerve is severe, the characteristic gait can be apparent immediately following injury, but more typically, a shoulder slip is not apparent for a few days to weeks after injury. Clinical signs do not indicate the degree of nerve damage, and there is no diagnostic method to determine the degree of recovery each horse will achieve.
Electromyography should be used to confirm that the suprascapular nerve, and not the brachial plexus, is the site of injury. Electromyography is only useful to evaluate nerve function from 7 days after injury on.

**Treatment**

**Conservative Management**

Conservative management consisting of box stall rest alone results in a good return to function. However, shoulder stability takes an average of 7 months to return. Surgical decompression of the suprascapular nerve can hasten the return of shoulder stability, diminish the amount of shoulder muscle atrophy, and return the horse to function sooner than that accomplished with conservative therapy alone. The potential for a modestly decreased time to function needs to be weighed against the costs and risks associated with surgery, especially given the potential for postoperative suprascapular nerve, and not the brachial plexus, is the site of injury. Electromyography is only useful to evaluate nerve function from 7 days after injury on.

**Scapular Nerve Decompression**

The horse is positioned in lateral recumbency with the affected limb uppermost. A 25-cm skin incision is made over the spine of the scapula and through the cutaneous trunci muscle. Fascia covering the spine of the scapula is incised, and the brachiocephalicus muscle is elevated from the spine of the scapula while preserving the fascia deep to the supraspinatus muscle to protect the suprascapular neurovascular bundle. The nerve is elevated from the scapula, and a small amount of bone is rasped off the cranial margin of the scapula. Care is taken to maintain smooth edges of the bone to decrease potential postoperative nerve injury. A tendinous band that limits the movement of the suprascapular nerve can be palpated on the medial side of the scapula and covering the nerve. This band should be incised to maximize nerve decompression from scar tissue. Incisional closure is routine, with attention to obliteration of dead space.

Assisted recovery from anesthesia is recommended given the shoulder instability and potential for fracture of the supraglenoid tubercle. The potential for postoperative fracture through the notch created in the scapula exists for 6 weeks postoperatively. Antibiotics and phenylbutazone are administered perioperatively, and low-dose phenylbutazone is continued for 3 to 5 days. Horses are confined to a box stall until shoulder stability is returned, typically 2 to 3 months. During stall confinement, muscle stimulation should be considered to minimize muscle atrophy. An intensive rehabilitation program then ensues to build shoulder strength prior to return to riding.

**Prognosis**

The prognosis for return to sound riding following conservative management or scapular nerve decompression is good. Atrophy of the supraspinatus and infraspinatus muscles might not completely resolve in all cases.

ANATOMY

The bones that make up the tarsus include the tibia, the talus and calcaneus, the central tarsal bone, the fused first and second tarsal bone, the third and fourth tarsal bones, and the metatarsal bones (MT II, III, and IV) (Fig. 99-1). The tarsal bones are maintained in intimate contact through their soft-tissue attachments, including the intertarsal ligaments, collateral ligaments, fibrous joint capsule, and plantar tarsal ligament. The medial collateral ligament connects the tibia and the proximal aspects of MT II and MT III, whereas the lateral collateral ligament consists of a long part connecting MT III and MT IV and a short part connecting the tibia to the calcaneus.

The tarsus is composed of five joints: the tarsocrural (TC), proximal intertarsal (PIT), distal intertarsal (DIT), tarso-metatarsal (TMT), and talocalcaneal (TCa) joints. Four of these five joints are almost immobile, and most of the movement of the tarsus is achieved in the tarsocrural joint. Micromovements occur during ambulation and weight-bearing in the three distal joints.

The three distal joints are often injected for diagnostic and therapeutic purposes. In one study, therapeutic cont-
The TCa joint in horses is a multifaceted structure consisting of three facets between the two bones involved: the facet at the medial aspect of the calcaneus and talus, the angulated coracoid facet of the lateral aspect of the calcaneus and talus, and the facet at the lateral aspect of the calcaneus facing medially and talus facing laterally, respectively. A strong interosseus ligament in the central tarsal sinus maintains the two bones in close proximity. The special relationship of the three facets relative to each other prevents motion in the joint.

Dorsally, the long digital extensor tendon spans the entire tarsal region and is maintained in position by the retinaculi. Just distal to the tarsal region, the lateral digital extensor tendon unites with the long digital extensor tendon. The strong fibularis tertius (peroneus tertius) courses parallel to the long digital extensor tendon (Fig. 99-2). At the level of the tarsus, it divides into medial, middle, and lateral branches before inserting on the central, third, and fourth tarsal bones as well as in the proximal metatarsal region. The medial part is better known as the cunean tendon, which at one time was thought to be responsible for the development of spavin. The fibularis tertius forms the cranial part of the reciprocal apparatus (Fig. 99-3). The gastrocnemius muscle and tendon form the caudal part. Interspersed between these two parts, the tibia and tarsus function as weight-supporting structures. The intact reciprocal apparatus ensures that when one of the major joints of the rear limb is flexed, all others flex.

Plantarly, the superficial digital flexor tendon passes under the tarsal retinaculum at the proximal aspect of the calcaneus and from there distally to the digit. The deep digital flexor tendon passes medial to the calcaneus over the sustentaculum tali. The tendon of the long digital flexor muscle traverses the tarsal region medially and joins the deep digital flexor tendon in the proximal metatarsal region.

The concentrations of methylprednisolone were measured in the DIT joint 6 hours after injection of methylprednisolone acetate into the TMT joint, confirming that communication between the TMT and DIT joints existed in 10 of 10 sampled joints (100%). In an earlier study communication was found between the TMT and DIT joints in four of 57 tarsi (7%); in one horse (2%), communication between the DIT and PIT could be established. In seven horses (14%), communication between the DIT joint and the tarsal canal existed, pointing out the potentially inconsistent results that can be found after intra-articular anesthesia. Other studies in the literature cite the communication between the TMT and DIT joints at 7% and 38%. Despite these conflicting reports, the most recent report is convincing to this author.

Figure 99-2. Correlation of the anatomic structures composing the reciprocal apparatus of the horse. a. Fibularis tertius tendon originating on the muscular fossa of the distal femur and inserting with the medial part on the central and third tarsal bones as well as at the third metatarsus (MTIII), whereas the lateral part courses towards the fourth tarsal bone. b. Gastrocnemius muscle, originating from the plantar fossa located at the distal aspect of the femur and the Achilles tendon, which unites with the soleus and accessory tendons before it inserts at the tuber calcanei.

Figure 99-3. Flexion of the tarsus or stifle results in flexion of all remaining joints in the hind limb.
All tendons pass over the tarsal region embedded in a tendon sheath. The tarsal canal is the largest tendon sheath and surrounds the deep digital flexor tendon.

The function of the tarsus is to transform axial loading during weightbearing from the cranioproximal to caudo-distal oblique forces exerted along the tibia into vertically and distally oriented forces through the metatarsal area.

**ACQUIRED DISORDERS OF THE TARSAL REGION**

Osteoarthritis is the most diagnosed acquired tarsal disorder causing lameness. It is seen in three forms: one involves the distal tarsal joints (referred to as bone spavin), one is located at the talocalcaneal joint, and the other involves the tarsocrural joint (referred to as bog spavin when joint distention is present; see Chapter 91). Other acquired disorders include fractures, luxations, and tendon and ligament injuries.

**Etiology**

OA of the distal tarsal joints is the most common cause of hindlimb lameness in the horse. The DIT and TMT joints are most often involved, but occasionally the PIT joint also is affected. A study in foals showed that bone density of the compact bone of the subchondral bone plate in the third tarsal bone reacts to variations in exercise at a very young age. Low bone density caused by lack of exercise was reversed when exercise was increased later. Osteoarthritic radiographic signs (enthesiophytes) in the distal intertarsal joints were common at 5 months of age and increased in severity until 11 months of age. Although the clinical relevance of these abnormalities in foals is uncertain, they might be related to the development of osteoarthritis in this region later in life.

Although the exact pathogenesis of distal tarsal OA is still unknown, compression and rotation of the distal tarsal bones, which occurs most forcefully at the gallop, can contribute to its development. Dressage horses, western horses, pulling horses, Standardbreds are prone to the disorder, which is associated with their type of athletic activity. Islandic horses are often affected, which is possibly related to the mismatch of the horse and the rider and the gaits at which these animals are used. The rack is a fast four-beat gait during which the horses place their hind limbs extremely far forward, and this extreme type of gait can be responsible for the development of bone spavin in these horses. Poor conformation also is a contributing factor to this disorder: bowlegged and sickle-hocked conformation results in abnormal loading of the small tarsal bones and leads to the development of OA.

Inciting causes of distal tarsal OA are septic arthritis, tarsal bone fractures, osteochondrosis, crushing of the central or third tarsal bones following incomplete ossification at birth, and excessive exercise. OA also has been associated with increased intramedullary pressure within the cuboidal bones of the tarsal region. Inciting causes for the less-often-encountered tarsocrural and to some extent talocalcaneal joint OA include intra-articular fracture, osteochondrosis, septic arthritis, and collateral ligament damage.

For most other tarsal disorders, external trauma, such as a kick from another horse or being hit by or running into an object, is the inciting cause. Repetitive trauma as it occurs during racing or competitive events in general can lead to the development of lameness.

**Clinical Signs**

The cardinal sign of a tarsal problem is lameness, which can vary depending on the severity, location, and acuteness of the disorder. Toe dragging is a common early sign that occurs because of a reluctance to flex the tarsus. Horses with OA often have a reduced foot flight arc, shortened cranial phase of the stride, gradual axial deviation in the flight path of the foot during the cranial phase of the stride, and a rapid abaxial deviation at ground contact. Affected horses often show pain to back palpation, and many horses are presented for a primary complaint of back pain. However, in most cases, a weight-bearing lameness is noted.

Joint distention is not a typical sign of OA of the distal tarsal joints, because the tarsal retinaculum over these small joints prevents its detection. However, new bone proliferation at the dorsomedial aspect of the limb might be noticeable in chronic cases (Fig. 99-4). A typical sign of a tarsocrural disorder is joint distention (bog spavin). However, as often noted in OCD, the swelling does not have to be painful.

An acute onset of a marked to severe weight-bearing lameness is a clear sign of trauma and is often associated

![Figure 99-4. Marked enlargement at the dorsomedial aspect of the tarsal region in a horse suffering from osteoarthritis of the distal tarsal joints (bone spavin). Excessive new bone formation is responsible for this appearance.](image-url)
with joint distention or swelling of the neighboring tissues, or both. Penetrating articular wounds lead in most cases to septic arthritis with all the accompanying signs including heat, swelling, and pain.

**Diagnosis**

The diagnosis of tarsal disorders involves a routine lameness examination, provided the animal is able to ambulate. In the presence of fractures and joint infections, the origin of which is often easy to localize, immediate attention should be given to the inciting cause, sidestepping the lameness examination. (This is not routine but an exception to the rule.)

Leading the horse in tight circles in both directions can exacerbate the lameness on the inside limb. Some horses initially show a marked lameness but with time warm out of it. Often the horse exhibits a barely detectable unevenness at the time of presentation or no evidence of lameness at all. A history that includes deterioration in the horse's attitude suggests subtle hock pain, which does not produce overt lameness. Evaluation of the shoes and looking for uneven wear can lead the clinician toward the diagnosis. Palpation of the tarsal region can allow detection of enlargement over the dorsomedial aspect of the tarsus; however, most lesions do not cause pain upon digital pressure. Cunean bursitis and effusion of the cunean bursa are rare, but they can be detected by palpation. Flexion tests often exacerbate the lameness.

Intra-articular anesthesia is a valuable aid in localizing the problem. Because there is controversy in the literature regarding communication between the TMT and DIT joints,3,4,6-18 each joint should be anesthetized individually. Significant improvement in lameness 10 minutes after intra-articular injection of 2 to 4 mL mepivacaine hydrochloride is diagnostic, but complete resolution of lameness might not occur because of intraosseous pain in the tarsal bones.13 Larger volumes of anesthetic should not be used because of the potential for periarticular extravasation and contact with nonarticular tissues, including the sensory nerve supply from the distal limb as it passes through the tarsus.16 In young racing Standardbreds, it might be advantageous to anesthetize the cunean bursa, because cunean bursitis is diagnosed in the these animals.

The joint region to be injected is clipped and prepared as for aseptic surgery. Meticulous cleansing of the area without clipping of the hair (application of the antiseptic of choice, scrubbing for 5 minutes followed by removal of the antiseptic soap, repeated twice) has no higher risk of iatrogenic joint infection following arthrocentesis than clipping the hair prior to preparation and needle placement (see Chapter 74).

The TMT joint is the easiest of the distal tarsal joints to inject (Fig. 99-5). The needle is inserted laterally, 0.5 cm proximal to the head of MTIV, in a dorsosomidistal direction at a 45-degree angle to both the sagittal plane and the ground until it makes contact with bone, usually at a depth of approximately 2 cm.15 This technique results in the needle tip's passing deep, medial, and slightly distal to the palpable lateral aspect of the head of MTIV, positioning it near the articulation between MTIV and the fourth tarsal bone. The steep angle is necessary to position the needle tip sufficiently distal to avoid penetrating the PIT joint, which is located only slightly proximal to the head of the MTIV.

The DIT joint is injected medially in the space between the central tarsal bone, the third tarsal bone, and the fused first and second tarsal bones (Fig. 99-6). The location for needle placement is found by palpation of the distal border of the cunean tendon, approximately 2 cm caudal to a vertical line extended distally from the medial malleolus.11 Ideally, the needle is inserted to the hub at a 45-degree angle in a plantarolateral direction and parallel to the ground.

Full penetration of a 2.5-cm needle in small horses can result in the needle's passing completely through the DIT joint and into connective tissue deep to the joint capsule.7 Also, the TMT joint can be entered inadvertently on the medial aspect of the tarsus while attempting to enter the DIT joint, because the TMT joint capsule is located just slightly distal to the DIT joint capsule.6 The PIT joint is rarely injected alone, because it communicates with the tarsocrural joint, and this injection is not discussed here.

The tarsocrural joint, of all joints composing the tarsus, is the easiest to inject, especially when it is distended. The dorsomedial pouch of the joint can be easily palpated. Taking care to avoid the saphenous vein, the needle is then inserted in a dorsocaudolateral direction, and depending on the degree of joint distention, 10 to 20 mL of synovial fluid is withdrawn prior to injection of 8 mL of mepivacaine hydrochloride.
Diagnosis is confirmed using standard radiographic views, including oblique projections. OA is commonly a bilateral condition; therefore, radiographs of both tarsal regions are recommended. Because some changes might be subtle, it is important to take good-quality radiographs. Lameness associated with the distal tarsal joints can exist with little or no radiographic abnormalities. Conversely, extensive radiographic changes might be present that are not associated with pain or lameness. Therefore, it is important to locate the site of lameness before obtaining radiographs. Fractures are best confirmed with good-quality radiographs. In rare cases, such as fractures of the central or third tarsal bones, this imaging technique does not provide evidence for an exact diagnosis.

Ultrasonography also can be used to arrive at a diagnosis as long as the lesions are peripheral. In-depth knowledge of the tarsal anatomy is a prerequisite if this imaging technique is applied. Scintigraphy has been used to localize lesions not visible on radiographs, especially in early cases where radiographic changes are not yet apparent. Computed tomography is rarely computed tomography necessary to localize a lesion. Computed tomography can be applied in the tarsus and provides valuable details for an exact diagnosis, especially in cases of hidden new bone formations and fractures. This technique is gaining in popularity.

**Treatment of Fractures**

Fractures of the tarsus, while rare because of the dense supporting structures that cover the bones in this area, occur when a significant external impact, such as a kick from another horse, is sustained in the tarsal region. Twisting and shearing of the tarsus while the lower limb is fixed can result in disruption of collateral and periarticular ligaments and subsequently lead to fractures.

**Distal Tibia**

Fractures of the distal tibia often involve the medial malleolus and can arise from external trauma, which results in avulsion of the medial malleolus from the tibia that is rarely accompanied by rupture of the medial short collateral ligament. Avulsion fractures of the lateral malleolus can occur as avulsions and involve the short and long lateral collateral ligaments. Avulsion fractures of the lateral malleolus are often comminuted. Arthroscopy can be used to remove fragments involving the medial malleolus; however, because of the soft-tissue coverage and intimate association with the joint capsule or lateral collateral ligaments, or both, lateral malleolar fragments can be removed more easily through an arthrotomy into the dorsolateral pouch of the TC joint or through a direct approach over the fracture through the lateral short collateral ligament, or a combination of these techniques and arthroscopy. If arthroscopy is attempted alone, the fragment might have to be divided into smaller pieces for removal using an osteotome and mallet.

Fragments larger than 3 cm are best reattached to the parent bone using 3.5-mm cortex screws placed in lag fashion. Large avulsion fractures of the medial malleolus can be repaired with one or two 4.5- or 5.5-mm cortex or cancellous screws placed in lag fashion (Fig. 99-7). A full-limb cast is applied for recovery from anesthesia and the initial postoperative period, if fixation rather than removal has been used.

**Figure 99-6.** Graphic illustration of the injection site for the distal intertarsal (DIT) joint. The DIT joint is injected medially in the proximal aspect of the space that exists between the central tarsal bone (e), third tarsal bone (d), and fused first and second tarsal bone (c). The entrance to this space can often be felt with firm palpation and is found at the distal border of the cunean tendon (a), approximately 2 cm caudal to a vertical line extending distally from the medial malleolus. The location for needle entry can also be located along a line between the distal tubercle of the talus (b) and the palpable space between the second metatarsus (MTII) (f) and MTIII, where it intersects the cunean tendon.

**Figure 99-7.** Dorsoplantar radiographic view of fixation of a medial malleolar fracture with two long cancellous screws and washers. Additionally, large fragments off the lateral trochlear ridge of the talus were reattached through three cortex screws, which were deeply countersunk into the articular surface.
Conservative management of nondisplaced distal tibial malleolar fractures is possible. Surgical management, either by removal of the fragment or by repair of the fracture, offers a favorable prognosis for return to previous performance levels in one report. However, an unfavorable to guarded prognosis was given in another report. A total of 4 to 6 months of rest is needed after surgery, particularly if fracture fixation was used as the surgical treatment.

**Trochlear Ridges of the Talus**

Fractures of the talus are acute injuries and are almost exclusively the result of external trauma such as a kick from another horse. The clinical signs vary considerably, depending on comminution, size, and displacement of the fracture. Significant effusion of the TC joint is seen with most fractures of the talus, and response to tarsal flexion is moderate to severe. Standard radiographic projections should be supplemented with flexed lateromedial and flexed lateromedial oblique projections and skyline views of the trochlear ridges. The distal aspect of the lateral trochlear ridge and the proximal aspect of the medial trochlear ridge (see Fig. 99-7) are most often affected.

Arthroscopic removal of small trochlear ridge fractures is generally the preferred treatment. The arthroscope portal for removing trochlear ridge lesions can be either dorsomedial or dorsolateral. The dorsolateral portal offers better visualization of the distal aspect of the lateral trochlear ridge, but the standard dorsomedial portal is preferred because triangulation is better and the surgeon can carry out a more thorough exploratory examination of the joint from a medial approach. The instrument portal is always dorsolateral and is usually slightly distal to that used for distal tibial lesions. Osteochondral defects or cartilage flaps might extend proximally along the lateral trochlear ridge, necessitating extension of the limb during surgery. Some surgeons prefer an arthrotomy approach directly over the lesion.

Large trochlear ridge fractures can be repaired with interfragmentary compression using several screws (Fig. 99-8). The fracture can be approached either through arthroscopy or an arthrotomy performed lateral to the ridge. After the fragment is identified and reduced, a glide hole is drilled perpendicular to the fracture plane from the dorsal aspect of the ridge. After preparing the thread hole, a deep countersink depression is prepared in the articular surface to accept the entire screw head. Therefore, it is better to use multiple 3.5-mm cortex screws, which have smaller heads, than to use 4.5- or 5.5-mm cortex screws. In large fragments, there is adequate solid bone to permit such a fixation. Anatomic reconstruction is a must if fixation is attempted. If this cannot be achieved, it is best to remove the fragment immediately to prevent the development of OA. Alternate fixation techniques include absorbable polydioxanone pins and cannulated screws.

Spurs or fragments associated with the distal end of the medial trochlear ridge of the talus (dewdrop lesions) are usually incidental findings and are not an indication for surgery, because they are usually extra-articular (Fig. 99-9). Arthroscopic removal has been described in the literature, although the technique is difficult because of extensive soft-tissue covering. For removal of these fragments, both the arthroscope and instrument portals are made in the dorsomedial pouch of the tarsocrural joint, with the instrument portal placed distal and slightly medial to the arthroscope.

Fragments off the proximal medial trochlear ridge are best removed arthroscopically (Fig. 99-10). With the horse in dorsal recumbency, the limb is positioned in flexion. With the joint distended, the arthroscope portal is made in the center of the caudolateral pouch of the TC joint. This approach provides good visualization of the talocalcaneal

---

**Figure 99-8.** A, A large, slightly displaced slab fracture of the lateral trochlear ridge. B, The fracture was repaired with three 3.5-mm cortex screws inserted perpendicular to the fracture plane. The screws were inserted from the articular surface, and the screw heads were completely countersunk. C, A two-year follow-up revealed no osteoarthritis in the joint. articulation, the proximocaudal aspect of the lateral trochlear ridge, the caudal aspect of the intermediate ridge of the tibia, and the medial trochlear ridge. Access to affected portions of the trochlear ridge can be accomplished as the degree of flexion is modified. The instrument portal is made in the caudomedial joint pouch using needle and visual guidance through the arthroscope.

Fractures of the distal lateral or medial aspect of the body of the talus occur rarely. Extreme angular forces need to be involved to cause such a fracture (Fig. 99-11, A). The animals are almost always non–weight-bearing lame and the tarsus is diffusely swollen. Radiography confirms the diagnosis. Conservative therapy in most cases is unrewarding. The horse shown in Figure 99-11 was readmitted for treatment after a year of limited pasture exercise because of continued lameness and pronounced joint distention of the tarsocrural and proximal intertarsal joint (see Fig. 99-11, B). The fracture subsequently was repaired with 3.5-mm cortex screws in lag fashion through an approach directly over the fragment. The lameness and joint distention resolved within 4 months postoperatively and the horse was returned to show jumping.

Recovery after surgery takes 8 to 10 weeks after arthroscopic removal of small fragments and 6 to 8 months or more if fracture repair is undertaken. Prognosis after fracture removal is favorable if soft-tissue damage at the time of injury is mild, secondary changes in the joint are minimal, and the fragment is shorter than 3 cm.23

Sagittal Fractures of the Talus

Sagittal fractures of the talus are rare.23,28 The medial fragment is usually smaller, and fractures can be repaired with two or three 4.5- or 5.5-mm cortex screws placed in lag fashion. The fracture can be approached from either the medial or lateral side.23,28 Arthroscopic visualization during the procedure is useful in assisting anatomic reduction of the fracture. Prognosis appears to be favorable if anatomic reduction can be achieved.23 Severely comminuted fractures of the talus are associated with severe soft-tissue trauma and destabilization of the TC joint and are inoperable in most cases.23

Calcaneus

Calcaneal fractures are often open and can be complicated by osteomyelitis, septic calcaneal bursitis, sequestration, and chronic drainage. Major fractures of the calcaneus can result in displacement of the superficial flexor tendon or can involve the sustentaculum tali. An open wound and local infection can eventually extend into the tarsal sheath. Lameness is usually severe with calcaneal fractures, and diagnosis is straightforward. In addition to standard projections, stressed radiographs can provide additional important information for diagnosis and management. Skyline views are useful for evaluating the tuber calcis and sustentaculum tali.

Small fragments distant from the calcaneal bursa can be removed through a direct approach or left to heal conservatively if they are not infected, but larger fragments should be repaired by lag screw fixation. Transverse fractures of the shaft of the calcaneus require application of one or two
narrow 4.5-mm limited-contact dynamic compression plates (LC-DCPs) or one broad 4.5-mm LC-DCP to the plantarolateral aspect of the bone. The superficial digital flexor tendon is reflected medially to allow placement of the plate, and the horse is recovered and maintained for 2 to 4 weeks in a full-limb cast that is removed with the horse standing. Removal of the implants after fracture healing can be helpful, but the overall prognosis to return to full performance for this type of fracture is guarded.

Fractures involving the calcaneal bursa in the presence of an open wound from a kick usually have a poor prognosis for future soundness. Invariably the bursa gets infected, and eventually the patient has to be destroyed for humane reasons. Aggressive treatment should be implemented as soon as possible after the injury has occurred and includes meticulous débridement of the wound, removal of the fragment, curettage of the fracture bed, lavage of the bursa, broad-spectrum antibiotics for 3 weeks, and placement of the limb in a cast for 3 weeks. Subsequently, a half-shell cast should be applied for an additional 3 weeks, followed by a Robert Jones dressing, provided the horse doesn't show signs of infection at an earlier time. If signs of infection are present, the wound needs to be evaluated immediately and the owner should be informed of the complication and the potentially grave prognosis. If a decision is made at that time to euthanize the patient, massive costs can be avoided.

Figure 99-11. A, Avulsion fracture of the lateral aspect of the distal talus with proximal intertarsal (PIT) articular involvement. The horse was managed conservatively with rest for one year. B, Marked joint distention visible in the tarsocrural and proximal intertarsal joints. a, dorsomedial pouch; b, plantarolateral pouch; c, lateral aspect of the proximal intertarsal joint. C, Postoperative radiographic view showing the fixation of the fracture with two 3.5-mm cortex screws. Six months later, the horse competed successfully in show jumping events.
Chip Fractures of the Sustentaculum Tali

Fractures of the sustentaculum tali occur rarely. These injuries are caused by acute trauma, mainly in the form of kicking injuries. The skin can be perforated, resulting in communication with the tarsal sheath of the deep digital flexor tendon. The animals are acutely lame and, depending on the duration of the injury and possibly associated tendon sheath infection, a grade IV lameness may be present.

Diagnosis is by a radiographic examination using multiple views. The proximodistal flexed view best delineates the sustentaculum tali (Fig. 99-12). Analysis and culture of the tendon sheath fluid is indicated. Treatment should be initiated immediately, especially when the tendon sheath is penetrated. Chip fracture removal can be achieved with arthroscopic technique, although one study suggests that many of the bony lesions might be outside of the tendon sheath and are best approached directly.31 Flushing of the tendon sheath with copious amounts of fluids is indicated after chip removal and careful curettage of the fracture bed. Tendovaginotomy and fragment removal represent another surgical approach.

Conservative management is contraindicated, especially in open injuries. Involvement of the sustentaculum is a key parameter in the decision for surgery. If the fracture involves a significant amount of the flexor surface, reattachment with cortex screws may be considered, especially if the tendon sheath was not penetrated at the time of injury. If treatment is delayed, proliferative changes can develop, leading to chronic lameness with a poor prognosis for future usefulness of the horse.

With immediate, effective treatment, a guarded prognosis for usefulness can be given. Neglected cases have a grave prognosis. Chip fracture removal can result in postoperative displacement of the deep digital flexor tendon, but this is rare.

Fractures of the Small Tarsal Bones

Slab fractures of the central or third tarsal bones occur after racing or other high-speed events. Fractures of the third tarsal bone are more common. Lameness is severe initially, but it diminishes over several weeks. Marked response to hock flexion persists over time, and persistent effusion of the TC joint is noted if the central tarsal bone is involved. When the central tarsal bone is fractured, intra-articular anesthesia of the TC joint partially alleviates lameness, but it can take 30 to 45 minutes for the maximal effect. Diagnosis of central and third tarsal bone fractures is confirmed with standard radiographic views but can require multiple oblique projections, because central tarsal bone fractures are often complex and comminuted.32 Radiographic confirmation of these fractures can be difficult. Nuclear scintigraphy and computed tomography are helpful when available.28,33

Screw fixation of slab fractures of the central and third tarsal bones is the treatment of choice (Fig. 99-13). The horse is placed in dorsal or lateral recumbency, and the fracture is compressed using one or two 3.5- or 4.5-mm cortex screws placed in lag fashion through stab incisions.

Figure 99-12. Flexed proximodistal radiographic view of the sustentaculum tali showing a chip fracture. The fracture was the result of a kicking injury to the medial aspect of the tarsus.

Figure 99-13. Radiographic view of a compression fixation of a slab fracture of the central tarsal bone. Lytic arthritis of the distal intertarsal joint is visible.
using intraoperative radiographic control. Conservative treatment (prolonged stall rest) has been successful, and some horses return to athletic use. However, treatment by screw fixation offers the best prognosis, because conservative management usually results in OA. Horses are rested for 4 to 6 months after surgery. Residual lameness can persist after either surgical or conservative management and eventually requires intra-articular medication, chemical or surgical arthrodesis (see Chapter 85), or screw removal after fracture healing.

**Treatment of Osteoarthritis**

**Osteoarthritis of the Distal Intertarsal Joints (Bone Spavin)**

Management of OA includes corrective shoeing, systemic and intra-articular anti-inflammatory medications, shock wave therapy, chemical and surgical arthrodesis, and cunean tenectomy.

**CORRECTIVE SHOEING**

Horses with bowlegged conformation profit from corrective shoeing in which the medial hoof wall is shortened and a special horseshoe with a wider, thicker outside branch is applied. The application of lateral wedges between shoes and hoof wall decreases tension on the medial patellar ligament and pressure on the medial side of the tarsal joint. However, the fetlock joint experiences considerably more stress. A recent study revealed that proper conditioning also can have a protective effect against bone spavin and lateral luxation of the patella.

**EXTRACORPORAL SHOCK WAVE THERAPY**

The systems used to apply extracorporal shock wave therapy in equine medicine are of the middle-energetic (0.2 ml/mm²) to high-energetic (0.4 ml/mm²) form. Therapy is generally applied in two or three sessions at approximately 3-week intervals. For treatment of soft-tissue calcifications, intervals between 3 and 6 weeks are used.

The skin overlying the target tissue is clipped or shaved. During application of the shock waves, horses are sedated. Depending upon the system used, a session takes 10 to 25 minutes. Some promising results have been achieved in the management of OA of the distal intertarsal joints, but insufficient clinical data are available to prove that there is a definite treatment benefit.

**MEDICAL MANAGEMENT**

**Nonsteroidal Anti-inflammatory Drugs**

Nonsteroidal anti-inflammatory drugs (NSAIDs) can be used as adjunctive medication during the convalescent period after surgery, but as a sole treatment for distal tarsal OA they are only palliative. As long the medication is administered, the lameness might be reduced or even absent, but as soon as administration is stopped, the lame ness returns.

**Corticosteroids**

Steroid treatment of OA involves intra-articular injection of long-acting corticosteroids into the involved joints (indicated only after diagnostic intra-articular anesthesia renders the animal free of pain or convincingly reduces the lameness). The TMT and DIT joints of both limbs can be treated simultaneously. With simultaneous treatment, the dose per joint should be reduced, because the total dose per horse should not exceed toxic levels (see Chapter 84 for specific drug dosages).

After injection, horses are rested for 2 or 3 days, after which work can be resumed. Most horses respond favorably to injection and are free of pain for several months. Aseptic technique is very important, because of the potential for inducing a postinjection flare or septic arthritis. A sudden onset of lameness within a few days of the injections should be managed immediately with joint lavage under general anesthesia. Oral anti-inflammatory therapy is indicated to maintain a reasonably comfortable patient during management of this complication.

Lameness usually recurs after a few weeks to months and can be managed by additional corticosteroid injections. In such patients, surgical or chemical fusion should be considered to maintain a useful horse.

**Hyaluronan and Polysulfated Glycosaminoglycan**

Hyaluronan and polysulfated glycosaminoglycan (PSGAG; Adequan) are used to improve the joint environment and reduce inflammation in high-motion joints (see Chapter 84). It is the author's opinion that these drugs can provide temporary relief for distal tarsal OA. However, if the patient is to be used in athletic competition, return of lameness is inevitable. Therefore these drugs do not have a place in the management of OA of the distal tarsal joints, especially if costs are considered.

**Chemical Fusion**

Chemical fusion of the DIT and TMT joints by intra-articular injection of sodium monoiodoacetate (MIA) was introduced as an alternative to surgical arthrodesis for horses clinically affected with bone spavin. MIA blocks a specific enzyme pathway in chondrocyte metabolism, resulting in chondrocyte death, cartilage necrosis, joint collapse, and fusion of the distal tarsal joints.

Horses receiving MIA should be premedicated with phenylbutazone (4.4 mg/kg IV q 12 hours) for 24 hours, beginning 12 hours before treatment. Injection with MIA should be preceded by contrast arthrography of each joint, because communication between the DIT and PIT joints and communication between the TMT and PIT joints has been documented. Using a 22-gauge 2.5-cm needle, joints are injected individually with 2 ml of diatrizoate meglumine, the needle is sealed with an injection cap, and dorsoplantar and lateral radiographs are taken immediately. After radiographs are taken, the needle is uncapped to allow the contrast medium to drain out of the joint. If contrast arthrography reveals no evidence of communication between the distal tarsal joints and the PIT joint, 100 mg of MIA in 2 ml of 0.9% saline solution and sterilized with a 0.2-μm syringe filter is aseptically injected into each joint. The DIT and TMT joints of both hindlimbs are routinely treated at the same time. Because of the danger of inadvertent periarticular injection, the procedure is performed best on the anesthetized horse (see Chapter 85).

Horses treated with MIA are likely to experience dramatic pain beginning 4 hours after treatment and lasting until
18 hours after treatment. Because of this, horses should be hospitalized after treatment and medicated for pain with butorphanol tartrate and detomidine hydrochloride as needed. Anesthesia of the tibial and peroneal nerves with bupivacaine hydrochloride is also an effective technique for managing transient pain after injection of MIA. Phenylbutazone is typically administered for 3 to 5 days after treatment, after which anti-inflammatory medications are usually unnecessary. Treated horses are exercised lightly the day following the injection, and these horses return to full work 2 days after the injection. Exercise sessions should consist of 45 to 60 minutes of full work in the horse’s discipline 5 to 6 days per week for 60 days after treatment to provide physical disruption of the articular surface.

SURGICAL MANAGEMENT

Cunean Tenectomy
Cunean tenectomy is a relatively simple procedure performed with sedation and local anesthesia. Cunean tenectomy can improve lameness by decreasing rotational forces on the tarsus that occur when the obliquely oriented cunean tendon tightens. This surgical treatment for acute OA is controversial. In instances when distal tarsal OA is chronic and bone proliferation under the tendon is excessive, this technique can provide some pain relief. The procedure can be performed bilaterally.

The surgical site is anesthetized by an inverted V-shaped line block spanning from the chestnut to the dorsal aspect of the saphenous vein. A 4-cm vertical skin incision is made over the cunean tendon approximately 5 cm dorsal to the chestnut, where the tendon is easily palpable (see Fig. 85-14). A 4-cm section of tendon is removed with a No. 15 scalpel blade, and the skin is sutured. A compression bandage is applied and changed as needed until the sutures are removed.

Aftercare consists of stall rest for 12 days with limited daily hand-walking. After the sutures are removed, the amount of hand-walking is increased gradually through the 21st postoperative day and includes walking over poles. Three weeks after surgery, riding starts over poles, and full work resumes at 6 weeks. This exercise regimen is important for preventing formation of restrictive scar tissue between the severed tendon ends and the cunean bursa.

Arthrodesis
Various surgical procedures are used to arthrodese the distal tarsal joints. Most procedures involve radiographically guided removal of cartilage by local drilling across part of the joint space. Bone plates, intra-articular stainless steel cylinders, transarticular screws placed in lag fashion, and cancellous bone grafts have been used to improve stability and hasten fusion after drill removal of cartilage and subchondral bone, but none of these treatments appears to offer substantial advantage to drilling alone.

Joint stability and pain relief can be obtained after bony bridging across only a small portion of the involved articular surface, which act as spot welds. Techniques have to be developed to provide better stabilization over a larger articular area, similar to the technique used for proximal interphalangeal arthrodesis, where a dorsal plate is supplemented by two screws that provide transarticular compression in the palmar region. However, in most of the currently used techniques, there is only a plate bridging the joints that are to be arthrodesed, and transarticular screws are avoided. Wyn-Jones and May also propose arthrodesis of the talocalcaneal joint with the help of four transarticular 5.5-mm cortex screws applied in lag fashion. The lameness associated with this fixation can be attributed to osteoarthrosis of the proximal intertarsal joint and occasionally with the tarsocrural joint. For more information please review Chapter 85.

Articular drilling is another method of surgical arthrodesis. Articular drilling is performed bilaterally on both the DIT and TMT joints as a single procedure. The technique is described in detail in Chapter 85. Drilling too deeply can cause penetration of the tarsal canal, resulting in unnecessary periosteal reactions or profuse hemorrhage if the perforating branch of the cranial tibial artery is inadvertently traumatized. Avoiding these complications is preferable, but they appear to have no effect on the success of the procedure.

Application of a four- or five-hole narrow dynamic compression plate (DCP) is described in detail in Chapter 85.

Aftercare
Horses can be lightly ridden 3 to 4 weeks after surgery. Administration of anti-inflammatory drugs maintains a reasonable level of comfort during the process of fusion. Most animals are free of lameness within 4 or 5 months of the procedure, but others show persistent lameness. Judgment on the outcome of the procedure is reserved until 12 months after surgery.
Prognosis
The prognosis for horses with distal tarsal OA treated with surgical arthrodesis is favorable, because most horses return to full function when the affected tarsal joints fuse. Return to soundness over a 3- to 12-month period is reported in 66.7% to 85% of horses undergoing arthrodesis of the DIT and TMT joints. Involvement of the PIT joint carries a less favorable prognosis because of its consistent communication with and concurrent involvement of the TC joint.

The prognosis following chemical fusion of the distal tarsal joints with MIA is favorable. Most horses show dramatic improvement in the original level of lameness within 1 week after treatment, even though fusion might not be apparent radiographically for 3 to 6 months (Fig. 99-15).

Thirty-nine horses with OA that was treated with intra-articular MIA were evaluated. Treatment was considered a short-term success when there was simultaneous documentation of radiographic fusion and soundness. At 1, 3, 6, and 12 months, success was achieved in 4 of 26 (8%), 15 of 27 (56%), 21 of 26 (81%), and 27 of 29 (93%) horses, respectively. Long-term evaluation showed that 16 of 16 (100%) horses had radiographic evidence of the treated distal tarsal joints, and 12 of 16 (75%) were free of lameness and the treatment was considered successful. OA of the PIT and TC joints was encountered in 4 of 39 horses (10%) and was diagnosed between 1 and 4 years after MIA treatment as acute severe lameness and swelling of the TC joint. Each horse was treated with MIA before the potential for communication between the DIT and PIT joints was recognized, and none received contrast arthrograms. It is presumed that such a communication existed, resulting in contact of MIA with cartilage of the PIT and TC joints.

The efficacy of cunean tenectomy is debated, and there are no controlled clinical studies or experimental evidence in the literature to either support or refute the validity of the procedure. An owner survey of 285 cases of bone spavin treated by cunean tenectomy showed that most owners (83%) believed that lameness and performance improved after cunean tenectomy and that they would have the procedure performed again.

Osteoarthritis of the Talocalcaneal Joint
The TCa joint has a curved contour, which is best recognized on lateromedial radiographs. The medial, lateral, proximal, and interosseous talocalcaneal ligaments support it. Osteoarthritis of the TCa is rarely described (Fig. 99-16). However, two reports have renewed the interest in this disorder. The clinical signs are not specific and resemble those of distal tarsal OA. Radiography and scintigraphy has been very beneficial in diagnosing the problem.

Conservative therapy is usually unrewarding. Stall rest, pasture exercise, and intra-articular corticosteroids with or without hyaluronan or PSGAG did not bring about consistent improvement of the lameness.

Surgical treatment involving partial tibial and fibular neurectomy cannot be recommended because of the poor results. Forage also did not result in improvement of the lameness. The best results were achieved with arthrodesis of the TCa joint.

Figure 99-15. A, Dorsoplantar radiographic view demonstrating fusion of the tarsometatarsal and distal intertarsal joints 6 months after injection with sodium monoiodoacetate. B, Gross anatomic specimen of the same horse after it was euthanized 1 month later for an unrelated reason. Solid bone bridging is obvious in certain areas.
Lameness of the tarsus can be associated with fractures. Luxations of the tarsus can be associated with fractures. Luxations usually occur at either the TMT joint or the PIT joint, but they occasionally involve the TC joint. Lameness is severe, with significant soft-tissue swelling, palpable instability, and crepitus. Luxations and subluxations of the tarsus might reduce spontaneously, but they can still be demonstrated with stressed dorsoplantar radiographs.

Luxations of the tarsus can be associated with fractures. The presence of fractures generally decreases the chances for a successful treatment. Open reduction and internal fixation is mandatory if fractures are present.

Luxations of the distal tarsal joints are best treated primarily with surgical arthrodesis, including débridement of the articular cartilage through an incision (if open, then on the open side of the joint), cancellous bone grafting, and joint stabilization with either trans-articular compression screws or bone plates (see Chapter 85). Horses with good temperaments and subluxations can recover for breeding purposes with only stall rest if they are kept tied on an overhead wire or in a rescue net to prevent them from lying down. Horses with luxations of the distal tarsal joints might return to soundness after joint fusion or arthrodesis, but luxation of the TC joint has a poor prognosis for athletic soundness because of joint and ligament damage.

Tarsal luxation is diagnosed as an acute traumatic event and can occur in any of the three distal tarsal joints or rarely in the tarsocrural joint. The animal is grade IV lame and might show an angular limb deformity in the tarsal region. However, lack of angular limb deformity does not rule out a luxation, because some luxations spontaneously reduce. Diagnosis is derived from palpation and a radiographic examination depicting the exact location of the injury (Fig. 99-17). In cases of reduced luxation, stress views should be taken under general anesthesia.

Tarsal luxation in the absence of major fractures can be treated with a full-limb cast for 3 months, with several cast changes during that time. This treatment is associated with the usual complications of prolonged cast applications, including pressure sores and cast disease.

Surgical arthrodesis of the TMT, DIT, and PIT joints has achieved superior results. The skin incision extends from the top of the calcaneus to the mid-MTIII on the plantarolateral aspect. The subcutaneous tissues are separated to expose the bone. The head of MTIV is trimmed with a chisel. An alternate approach involves removing the entire MTIV (see Chapter 85). A 12-hole 5.5-mm LC-DCP is contoured to the bones and applied with 5.5-mm cortex screws (see Fig. 99-17). Solid purchase of each screw in healthy bone is of great importance with this fixation. Therefore, the direction of each screw through the corresponding plate hole has to be carefully selected using radiographic control. It is important to insert several oblique transarticular screws across the luxated joint to provide additional stability.

After the subcutaneous tissues and skin are closed, a full-limb cast is applied for the initial 2-week period, after which a Robert Jones bandage is applied for 2 to 3 additional weeks. Hand-walking can be started after 2 months, and light riding can be resumed after 3 months. Full recovery is expected, barring no postoperative complications, such as infection or implant breakdown.

**Treatment of Tendon Disorders**

**Luxation of the Superficial Digital Flexor Tendon**

Superficial digital flexor (SDR) tendon luxations are seen in three forms in decreasing frequency: lateral displacement with disruption of the medial retinaculum, medial displacement of the lateral attachment, or splitting of the SDF tendon with a portion lying on either side of the tuber calcis. The etiology can be direct trauma or excessive strain during partial flexion.

Diagnosis of acute SDF tendon luxation can be difficult because of swelling, but palpation and observation during flexion and extension usually allow a diagnosis. Ultrasonography is the diagnostic aid of choice. Sometimes dislocation occurs only during motion, and the tendons maintain appropriate alignment when the limb is at rest. In more chronic cases of permanent luxation, the metacarpophalangeal joint can be hyperextended during weightbearing...
compared to the other limb. This occurs when the SDF tendon bypasses the tuber calcis in a course that is in a straighter line, which makes it functionally too long.

Partial or intermittent dislocations can heal with stall rest, with or without the benefit of a bandage or full-limb cast. Rest for 4 to 6 months is necessary. Despite a clinical report claiming that conservative management allows a successful return to athletic competition, the general thought is that surgical repair is mandatory for return to athletic function.

The horse is placed in dorsal or lateral recumbency to allow exposure of the damaged side of the tarsal retinaculum. After débridement of the edges, horizontal mattress sutures are pre-placed on both sides of the defect well back from the defect margin. The ruptured ends are subsequently apposed and closed with interrupted horizontal mattress sutures of no. 0 monofilament absorbable material. A synthetic mesh graft is sutured over the defect using the pre-placed sutures.

After the incision is closed, the limb is placed in a full-length cast for recovery. Support of the repair can be provided by placement of bone screws into the calcaneus opposite the tear to provide a buttress against repeated dislocation. Confinement for 4 to 6 months is necessary to allow for sufficient fibrosis.

Prognosis with surgical management diminishes as the anticipated level of performance increases. Prognosis for athletic soundness with conservative management is guarded for complete displacement, but it is favorable for cases involving partial rupture of the retinaculum. Medial dislocations have a better prognosis than do lateral displacements.

**Displacement of the Deep Digital Flexor Tendon**

Luxation or displacement of the deep digital flexor (DDF) tendon is a rare congenital anomaly. In this condition, the DDF tendon is located axial to its normal position and not within the groove formed by the sustentaculum tali. The malpositioned DDF tendon exerts a medial pull on the distal limb, and the first recognizable clinical sign is a varus deviation of the tarsus noted at 2 to 4 weeks after birth. Diagnosis is based on palpation, ultrasonography, and skyline radiography of the tarsus that demonstrates hypoplasia of the sustentaculum tali. Surgery to replace the DDFT in its normal position and augment the sustentaculum tali has been recommended.

The foal is placed in lateral recumbency with the affected limb down. The DDF tendon and its tendon sheath are exposed from 10 cm proximal to 10 cm distal to the tarsus and freed from all soft-tissue attachments. The tendon sheath and tendon are placed back in the groove of the sustentaculum tali and sutured to underlying tissue. A cortical bone graft obtained from a rib is subsequently fixed onto the sustentaculum tali with bone screws to resist further medial displacement, and the incision is closed routinely. A cast is not necessary for recovery. Confinement is recommended for 4 weeks, and the prognosis for eventual soundness is good.

**Tenosynovitis of the Deep Digital Flexor Tendon**

Chronic irritation and tenosynovitis of the DDF tendon can be a sequela to sustentaculum tali injury. Radiographically, new bone proliferations (Fig. 99-18, A) can be seen in the
region, leading to tendon sheath distention (Fig. 99-18, B) and possible ossification. Contrast tenography can provide valuable information on the pathology present within the sheath.

Treatment of these problems involves tenoscopic exploration of the pathology and removal of any proliferative changes. Tendovaginotomy represents an alternate approach. However, chronic degenerative changes of the sustentaculum tali and overlying DDF tendon have a guarded prognosis for resuming normal work. After closing the skin incision in routine fashion, a pressure bandage is applied and maintained for 3 weeks. Intratendovaginal hyaluronan 1 week postoperatively is indicated.

Avulsion of the Gastrocnemius
Rupture of the gastrocnemius muscle occurs occasionally in foals and young horses. The disorder can be caused by external trauma or excessive running in the field, possibly associated with slipping or sudden unexpected turns. The diagnosis is straightforward, because the reciprocal apparatus is not functional. As the animal places weight on the limb, the tarsus collapses distally, and the stifle joint becomes extremely extended (Fig. 99-19, A).

Ultrasonography usually finds the gastrocnemius tendon intact but the origin of the muscle avulsed from the distal and caudal aspect of the femur. The avulsion can be complete or partial. Partial avulsion causes only slight dropping of the tarsus during weightbearing.

Management involves maintenance of a full-limb Robert Jones bandage with an incorporated splint for several weeks. An alternate treatment is application of a tube cast over the tarsal region (Fig. 99-19, B) for 3 weeks, followed by a Robert Jones bandage for an additional 3 to 5 weeks.

Both partial and complete avulsions have a favorable prognosis for a competitive future. Complications include all problems encountered with long-term casting and bandaging of the tarsal region.

DEVELOPMENTAL DISORDERS OF THE TARSAL REGION
Osteochondrosis
Etiology
Osteochondrosis (OC) in the equine tarsus occurs most commonly in the distal intermediate ridge of the tibia (Fig. 99-20, A), followed by the lateral trochlear ridge of the talus (see Fig. 99-20, B), the medial malleolus of the distal tibia, the medial trochlear ridge of the talus, and the lateral malleolus of the distal tibia. Subchondral cystic lesions (see Chapter 92) have been identified in the distal tibia and talus, but they are considered unusual. These lesions also have been identified in the cuboidal bones of the distal tarsus and are associated with an inflammatory reaction.

Osteochondrosis results from failure of endochondral ossification or loss of blood supply to immature cartilage and subchondral bone and can be influenced by various factors, including exercise, hormone imbalances, nutrition, heredity, and conformation (see Chapter 91). Heritability estimates suggest that 25% to 52% of the variation in occurrence of OC in the hock can be attributed to genetic factors. Others conclude that distal tibial lesions arise from biomechanical trauma early in life or represent supernumerary ossification centers that are not part of the OC complex. One study documented 11 of 77 foals with obvious distal tibial fragments that were radiographically normal by 8 months of age.

Diagnosis
Signs of tarsocrural OC are usually associated with the onset of training. Synovial distention is the most common manifestation of the condition, sometimes followed by mild lameness (identified in only 66 of 144 affected limbs). Pain on flexion of the tarsus is usually mild, and synovial fluid analysis is rarely indicated. Four standard radiographic views of the tarsus should be taken, but flexed views may...
Figure 99-19. Three-week-old Quarter Horse foal with an avulsion of the gastrocnemius muscle. A, Weightbearing results in marked dropping of the tarsus and extension of the stifle. B, Application of a tube cast over the tarsal region allows the foal to bear weight.

Figure 99-20. A, Dorsomedioplantarolateral oblique (DMPLLO) radiographic view of the tarsus showing a distal intermediate ridge of the tibia OC lesion (arrows). B, DMPLLO xeroradiographic view of the tarsus showing a lateral trochlear ridge OC lesion. (Courtesy C. W. McIlwraith, Colorado State University.)

also be useful to demonstrate loose fragments or osteochondral defects in the caudal aspect of the joint. Bilateral lesions involve the distal tibia 20% to 45% of the time. Distal lesions of the tibia vary dramatically in size, ranging from small fragments less than 5 mm in diameter to involvement of the entire intermediate ridge. OC lesions can be identified arthroscopically without radiographic evidence of their presence. These horses might or might not be presented with synovial effusion.

Treatment
Arthroscopic removal of tarsocrural OC fragments is the treatment of choice, particularly if clinical signs of effusion...
or lameness are noted. Horses without clinical signs associated with radiographic evidence of OC can develop osteoarthritis of the TC and PIT joints and linear erosions along the side walls of the trochlear groove of the talus later in life. Arthroscopic examination of the TC joint in mature horses with OC often reveals fibrillation of articular cartilage. These findings suggest that early surgical intervention is warranted to minimize secondary joint changes.

DISTAL INTERMEDIATE RIDGE OF THE TIBIA

The horse is placed in dorsal recumbency with the limb in slight flexion. The arthroscope portal is made on the dorsal aspect of the dorsomedial pouch of the tarsocrural joint, centered over the pouch (Fig. 99-21). Placement of the arthroscopic portal too far medial makes it difficult to pass over the medial trochlear ridge, and placement too proximal or too distal also will jeopardize visualization. It is best to identify the saphenous vein before synovial distention and avoid it.

After the joint is distended, a stab incision is made through the synovial membrane, and the arthroscopic sleeve is inserted into the joint with a conical obturator. The limb is placed in 90 degrees of flexion, the arthroscope is inserted, and the joint is explored (Fig. 99-22, A).

The location of the instrument portal can be identified by passing the arthroscope laterally over the proximal aspect of the exposed lateral trochlear ridge into the dorsolateral pouch and palpating the tip through the skin. This procedure is also useful to demonstrate a vessel in the area by back-lighting it with the arthroscope when the surgery room lights are dimmed. Alternatively, a needle can be inserted through the dorsolateral pouch and advanced until it makes contact with the lesion. Insertion of a hypodermic needle at the intended site allows the exploration of the range of motion possible with the instrument.

Once the ideal location is determined, a skin incision is made along the needle. A no. 11 scalpel blade is advanced into the joint along the needle, and a small incision is made into the synovial membrane. The needle and scalpel are removed and immediately exchanged with the arthroscopic probe. Intermediate ridge fragments may be loosely attached and elevated with the probe or may be firmly attached to the distal tibia, requiring partial separation with a periosteal elevator (Fig. 99-22, B) or an osteotome and mallet. Care should be taken not to damage the articular cartilage on the lateral trochlear ridge with the elevator or osteotome. After elevation, fragments are grasped with rongeurs, rotated to divide any remaining attachments, and removed. The sur-

Figure 99-22. A, Arthroscopic view of a distal intermediate ridge (OC) lesion. B, Partial separation of the OC fragment from the distal tibia with the help of a periosteal elevator. These lesions are attached in most cases to the tibia by fibrous connective tissue.
LATERAL TROCHLEAR RIDGE

The arthroscope portal for removing lateral trochlear ridge lesions can be either medial or lateral. The lateral portal offers better visualization of the distal aspect of the lateral trochlear ridge, but the standard medial portal is preferred because triangulation is better and the surgeon can carry out a more thorough exploration of the joint from a medial approach. The instrument portal is always lateral and is usually slightly distal to that used for distal tibial lesions. Both distal intermediate ridge and lateral trochlear ridge lesions can be treated with a single instrument portal when found concurrently within a single joint (see Fig. 99-21). Osteochondral defects or cartilage flaps can extend proximally along the lateral trochlear ridge, necessitating extension of the limb during surgery. Some surgeons prefer an arthrotomy approach directly over the lesion, but it is not recommended.9,25

PROXIMAL INTERTARSAL JOINT

Loose fragments, usually shed from the intermediate ridge of the distal tibia, can lodge in the dorsal pouch or dorsal joint capsule of the PIT joint. Although rarely of clinical significance, these fragments can be removed, if they are loose, by arthroscopically inserting an instrument into the pouch to blindly grasp the fragment or manipulate it into the TC joint for removal. Because of their limited clinical significance and the relative difficulty of finding and removing the fragments, it has been recommended that they be removed only if this can be easily accomplished during surgery for the primary lesion of the TC joint.58

Aftercare

Stab incisions are closed with skin sutures only. Bandages are applied and maintained for 21 days after surgery and are changed as necessary. Sutures are removed 14 days after surgery. Exercise is restricted to hand-walking for 4 to 8 weeks, and training can be resumed in 8 to 16 weeks, depending on the severity of the lesion and the amount of synovial distention before and after surgery. Postsurgical administration of phenylbutazone, hyaluronan, or PSGAG is useful to help resolve effusion, particularly in horses with prolonged synovial distention before surgery.

Prognosis

It is generally accepted that the prognosis for athletic soundness is improved with surgery compared to conservative management.78,79,80 Seventy-seven percent of horses with OC of the tarsus raced successfully or performed their intended function following arthroscopy.58 However, the prognosis decreases when articular cartilage degeneration or erosion is noted at the time of surgery. In one study,58 resolution of synovial effusion after arthroscopy was higher in racehorses (83%) compared to non-racehorses (74%), and it was more likely with lesions of the distal tibia compared with other locations. There was no significant relationship between resolution of the effusion and successful performance outcome.58

Reports on the effects of OC on racing performance are contradictory. Although one study found no difference in the racing performance of Standardbreds demonstrating OC

MEDIAL MALLEOLUS

The arthroscope portal for medial malleolus lesions is made more ventral (more distal on the limb) than for intermediate ridge lesions to minimize the risk of accidentally pulling the arthroscope out of the joint during visualization. The instrument portal (also ventromedial) is identified by prior insertion of a needle. Techniques for removing fragments are similar to those used for other lesions in the TC joint.

Figure 99-23. Lateromedial radiographic view of a tarsal region showing a loose fragment at the distal aspect of the joint cavity (white arrow). The origin of the fragment is the distal intermediate ridge of the tibia (black arrow).
lesions compared with a radiographically normal control population.86 another study reported that horses with OC of the TC joint had significantly fewer starts and lower earnings compared with horses without radiographic changes.82 A third study found that the number of racing starts and race earnings for horses with surgically treated tarsocural OC was reported to be lower than for age-matched siblings,83 but a fourth study found that horses treated arthroscopically for OC of the distal tibia performed no worse than did their matched controls.84 Despite these reports, the author recommends surgical treatment of this condition in all types of horses to prevent the development of OA in the TC joint.

Angular Limb Deformities
Angular limb deformities of the tarsus are seen less often than in the carpus or forelimb fetlocks, but they are diagnosed and treated in a similar fashion. Tarsus valgus is by far the most common presentation and can be caused by ligamentous laxity, malformation or incomplete ossification of the cuboidal bones of the tarsus, physical dysplasia, or uneven growth of the distal tibial plax. A complete discussion of the etiology, diagnosis, and treatment of angular limb deformities can be found in Chapter 89.

Dextrose, for hypertonic dehydration, 28
Dextran, 275, 276f
Dexamethasone
for sedation of foal, 230-231
for rectal tear repair, 484, 486, 486f
Desflurane, cardiorespiratory effects of, 221
Desmotesomy, of accessory ligament of deep
gastrocnemius tendon, 1066-1107, 1106f
Desmin of accessory ligament of deep digital flexor
tendon, 960, 962f, 109f
of collateral ligament, 954, 955f
of impar ligament, 952-953, 954f
of navicular suspensory ligament, 951-952, 953f
of proximal suspensory ligament, 958, 960,
961f, 962f
faciotomy and neuroectomy of deep
branch of lateral plantar nerve for,
1086-1107, 1106f
of sesamoid ligament, oblique and
straight distal, 958, 959f
of suspensory ligament, 958, 960f
Desmosomy of accessory ligament of
deep digital flexor tendon, 1106-1107, 1106f
of deep digital flexor tendon
in distal interphalangeal joint
contacture management, 1159-
1160, 1160f
in metacarpophalangeal joint
contacture management, 1162
of superficial digital flexor tendon
for strain-induced tendinitis, 1102-1103,
1104f
of superficial digital flexor tendon,
in metacarpophalangeal joint
contacture management, 1162-
1163, 1163f
of annular ligament, for strain-induced
tendinitis, 1106, 1106f
medial patellar, 1325-1326
of suspensory ligaments (DSL), for
navicular syndrome, 1211-1212,
121f, 121f
Detomidine
dosages of, during recovery, 240t
for epidural analgesia, 250t
infusion dosages of, 247t
for sedation of foal, 230-231
Desxamethasone
dosages of, during recovery, 240t
for endotoxemia, 17-18
Dextrose, for hypertonic dehydration, 28
Diagnostic anesthesia, in lameness evaluation,
901-922. See also Lameness, evaluation of,
diagnostic anesthesia in
Diaphragmatic hernias, 420-421, 496, 498,
498f
INDEX
Cycloxygenase 2 (COX-2) inhibitors, for
ostearthritis, 1064-1065, 1064f
Cyclosporine A, sustained-delivery devices for
intravitreal, 750, 750f
Cysteine of bone, subchondral, 1178-1184. See also
Subchondral cystic lesions (SCLs).
Dextrose, for hypertonic dehydration, 28
for endotoxemia, 17-18
Diazepam
for sedation of foal, 230-231
for rectal tear repair, 484, 486, 486f
Desflurane, cardiorespiratory effects of, 221
Desmotesomy, of accessory ligament of deep
gastrocnemius tendon, 1066-1107, 1106f
Desmin of accessory ligament of deep digital flexor
tendon, 960, 962f, 109f
of collateral ligament, 954, 955f
of impar ligament, 952-953, 954f
of navicular suspensory ligament, 951-952, 953f
of proximal suspensory ligament, 958, 960,
961f, 962f
faciotomy and neuroectomy of deep
branch of lateral plantar nerve for,
1086-1107, 1106f
of sesamoid ligament, oblique and
straight distal, 958, 959f
of suspensory ligament, 958, 960f
Desmosomy of accessory ligament of
deep digital flexor tendon, 1106-1107, 1106f
of deep digital flexor tendon
in distal interphalangeal joint
contacture management, 1159-
1160, 1160f
in metacarpophalangeal joint
contacture management, 1162
of superficial digital flexor tendon
for strain-induced tendinitis, 1102-1103,
1104f
of superficial digital flexor tendon,
in metacarpophalangeal joint
contacture management, 1162-
1163, 1163f
of annular ligament, for strain-induced
tendinitis, 1106, 1106f
medial patellar, 1325-1326
of suspensory ligaments (DSL), for
navicular syndrome, 1211-1212,
121f, 121f
Detomidine
dosages of, during recovery, 240t
for epidural analgesia, 250t
infusion dosages of, 247t
for sedation of foal, 230-231
Desxamethasone
dosages of, during recovery, 240t
for endotoxemia, 17-18
Dextrose, for hypertonic dehydration, 28
Diagnostic anesthesia, in lameness evaluation,
901-922. See also Lameness, evaluation of,
diagnostic anesthesia in
Diaphragmatic hernias, 420-421, 496, 498,

### INDEX

**Equine recurrent uveitis (ERU)**, 749-755

**Equine cutaneous mastocytosis (ECM)**, 314-315

**Equilibrium, hindbrain and**, 637-638

**Epithelialization, in wound repair**, 49-50

**Epineurial repair, of peripheral nerve injury**, 1135

**Epinephrine, in hemorrhage control**, 158

**Epidural analgesia**, 249-250, 250f, 250t

**Epididymis, anatomy of**, 775-776, 775f

**Epidermis**, 288, 288f

**Epidermal inclusion cysts, of nares**, 534

**Epidermal growth factor, wound repair and**, 1150

**EO (ethylene oxide), for sterilization**, 115-116, 115f

**Enzymatic débridement, of superficial wounds**, 291-292

**Enzymatic activities, detection of**, 985

**Enucleation**, 760, 761f, 762-763

**Entropion**, 704-705, 704f, 705f

**Entrapment of epiploic foramen (EFE)**, 413-414, 413f, 414f

**Entropion, position and movement of, in neurologic examination**, 647

**Erythromycin, for postoperative ileus**, 504-505

**Erbium laser**, 177t

**Erection**

**Erectile bodies**, 811-813, 812f

**Erection clinical examination of**, 815

**Elevation mechanism of**, 813

**Erection, persistent**, 813-814

**Ectropion surgical anatomy of**, 692-774

**Eyes, position and movement of**, 1135

**Eyeball, position and movement of**, 1135

**Eyedrops, antibiotic fortified, preparation of**, 1150

**Eye(s)**

**Facial nerve (VII)**, 637, 638

**Facial expression, hindbrain and**, 637

**Face masks, for operating team**, 131-132, 132f

**Face, clinical examination of**, 703

**Face, diagnostic procedures for**, 703-704

**Face, distichiasis of**, 706-707

**Face, ectropion of**, 705-706

**Face, entropion of**, 704-705, 705f

**Face, epibolism of**, 706-707

**Face, euthanasia of fracture patient**, 1140

**Face, eyelid(s)**

**Facial nerve (VII)**

**Facial expression, hindbrain and**, 637

**Face masks, for operating team**, 131-132, 132f

**Face, clinical examination of**, 703

**Face, diagnostic procedures for**, 703-704

**Face, distichiasis of**, 706-707

**Face, ectropion of**, 705-706

**Face, entropion of**, 704-705, 705f

**Extracorporeal shock wave therapy (ESWT)**

**Extubation of epipharynx (EFE)**, 413-414, 413f, 414f

**Epiploic foramen, entrapment of**, 413-414, 413f, 414f

**Epinephrine, in hemorrhage control**, 158

**Epineurial repair, of peripheral nerve injury**, 1135

**Epidermis**, 288, 288f

**Epidermal inclusion cysts, of nares**, 534

**Epidermal growth factor, wound repair and**, 1150

**EO (ethylene oxide), for sterilization**, 115-116, 115f

**Enzymatic débridement, of superficial wounds**, 291-292

**Enzymatic activities, detection of**, 985

**Enucleation**, 760, 761f, 762-763

**Entropion**, 704-705, 704f, 705f

**Entrapment of epiploic foramen (EFE)**, 413-414, 413f, 414f

**Entropion, position and movement of**, 1135

**Eyeball, position and movement of**, 1135

**Eyedrops, antibiotic fortified, preparation of**, 1150

**Eye(s)**
INDEX
Incisor(s) (Continued) wounding of, 1343-1345, 1344f, 1345f, 1346f, 1347f overjet/overbite and, 322, 323f, 325f retained deciduous, 324, 325f supernumerary, 324 underbite and, 324 wear of, abnormalities of, 325 Inclusion cysts, epidermal, of nares, 534 Incompetence, cervical, 835 Infarction(s) cecal, 446 hemorrhagic, of small intestine, 406 mural, 461, 461f small colon, nonstrangulating, 470 splenic, 381 Infection(s) bicipital bursa, 1285 in chronic wounds, 303-304, 303f clostridial, complicating testicular surgery, 805 complicating fracture healing, 998 complicating ulcer fracture, 1272 complicating ventral body fusion, 673 implant removal due to, 1027 incisional, 509 microorganisms causing, sources of, 70-72 nosocomial, in surgical patient, 70-71 postoperative, 508 repair and, 54t, 55-56 Inflammasome, for surgical site infections, 30 Inflammation acute, in wound repair, 45-47, 46f, 47f after intraocular surgery, 745 intestinal, 412 Inflammatory phase, in fracture healing, 996 Inflammatory reaction, in tendon repair, 1093, 1093f Inguinal approach for cryptorchid castration, 795-796, 796f, 797f for acute abdomen, 394, 394f to cryptochitid castration, 795-796, 795f, 797f, 798f Inguinal hernia, anatomy of, 776 Inguinal incision, for castration, 791 Inguinal incision for cryptorchid castration, 795-796, 795f, 797f, 798f repair of, 800, 802 Inguinal incisions, for castration, 791 Inhalation anesthesia, 219-223. See also Anesthesia, Inhalation. Injection anesthesi, 223-226. See also Anesthesia, injection. Injection, subcutaneous, in application of ophthalmic medications, 700-701 Insolation, in skin graft acceptance, 270 Instruments for caudal reproductive tract surgery, 838, 838f, 839f for corneal surgery, 735 for cryosurgery, 173-174, 173f, 174f, 175f for materials, for metallic, 104-105, 104f, 105t, 105t for ophthalmic surgery, 696-697, 696f, 697f preparation of, for sterilization, 112-114 for scleral surgery, 735 for split-thickness graft, 274-275, 275f surgical, 134-151 basic manipulations of, 151-153, 152f, 153f for endoscopy, 164-165, 165f, 166f foreps as, 139-141, 140f, 141f, 142f, 143f general, 135-146 identification of, 150 maintenance of, 149-150 materials for, 135t microsurgical, 148 needle holders as, 139, 139f orthopedic, 146-148, 147f, 148f, 149f pack preparation for, 150-151 Instruments (Continued) retractors as, 141-142, 144-146, 144f scalps as, 136-137, 136f, 137f scissors as, 137-139, 138f, 139f storage of, 150-151 suction tips as, 146, 146f towel clamps as, 146, 146f for urinary tract surgery, 867 Insulin-like growth factors (IGFs), wound repair and, 54t, 55-56 Integumentary system, 254-320. See also Skin. Interferons (IFNs), wound repair and, 53, 54t Interleukins, in osteoarthritis, 1049 Internal fixation, of fractures, 1006-1027. See also Fracture(s), internal fixation of. Interphalangeal joint distal. See Distal interphalangeal (DIP) joint, proximal. See Proximal interphalangeal (PIP) joint. Interrupted suture patterns, 193, 193f, 195f in reconstructive surgery, 258 Intesex, 784-785, 784f Intersubjectivity, 822 Intestinal anastomoses, 425-426 Intestinals, postoperative, 428, 502-506 Intertubercular bursa, of shoulder, pathologies of, 1285 Intestines injury to, mechanisms of, 396-398 large, 436-478. See also Cecum. Large (ascending) colon, Small (descending) colon obstruction of, 395-396, 401-436. See also Small intestine. viability of, determination of, 398-400 Intra-arterial analgesia, 1249 Intra-articular fractures arthroscopic reconstruction of, 1056 osteochondral, prognostics for, 1059f prognosis for, 1060f. Intraocular fluid (ICF), 20, 21f Intradermal injection, of nasopharyngeal masses, 549 Intraocular interlocking nail (INO), in fracture fixation, 1025-1026, 1025f Intraocular nails, in fracture fixation, 1025-1026 Intraocular pin plate (IMPP) technique, for MCT/MITD arthrodesis, 1080 Intraorbital pins, for mandibular fractures, 1348 Intramuscular cyst, of esophagus, 369-370, 369f, 370f Intramuscular hemoma, small colon, 469-470 Intramuscular suture pattern, 194f, 197f Intracaudal prosthesis, 749 Intracaudal surgery, 744-749 anatomy for, 744-745, 745f diagnostic procedure for, 746, 746f disorders managed by, 746-749, 747f immunology and, 745 pars plana vitrectomy as, 752-754, 753f, 754f Intracranial prosthesis, 763 Intracranial pressure, osteoarthritic pain and, 1050 Intrascleural implant, 763 Intravenous anasthesia in foelined, 909, 915f, 917f, 918f in hindlimb, 909, 919f, 920f, 921f-922f Intravenous catheters, for fluid therapy administration, 29-30, 30f Intrinsic pathway, of coagulation, 34, 34f Intubation, nasogastric, in colic, 388f Intranasal insufflation cocciceal or cocceicol, 443-446, 445f of small colon, 471 small intestinal, 415-417, 416f, 417f Inverting suture patterns, 193, 194f, 196f Ion absorption, intestinal, 402-403
INDEX

1375

Keratoplasty (Continued)
posterior, 740-741, 740f
penetrating, 739-740, 740f
perforating, 737
Kessler suture pattern, modified, 194, 197f
Ketamine
in anesthesia induction, 223-224, 224f
for central sensitization, 248-249
for epidural analgesia, 250f
infusion dosages of, 247f
Ketoprofen, for musculoskeletal pain, 1065t
Kemical gait analysis, 894, 896f
of lame horse, 895, 897
Kinetin gait analysis, 894-895, 897f
of lame horse, 897-898

Kinetic gait analysis, 894, 896f
of lame horse, 895, 897
Kinetic gait analysis, 894-895, 897f
of lame horse, 897-898
Knots, suture, 191-193, 192f
Krypton laser, 177t
KTP laser, delivery system for, 183, 183f
Laceration(s)
cervical, from foaling, 852-853, 852f
conjunctival, 720
corneal, 737-738, 769-771, 770f, 771f
of hoof, 1196
nasolacrimal system, 728-729, 730f
perineal
bladder eversion and, 880-881, 881f
from foaling, 845, 847-848, 847f, 848f
single-stage repair of, 847, 850f
two-stage repair of, 847-848, 849f, 850f
scleral, 737-738
tendon
clinical characteristics of, 1098, 1098f
emergency treatment of, 1107
surgical repair of, 1107-1109, 1107f, 1108f
third eyelid, 724
urethral, 869-869
Lactate
in blood gas analysis, 25
blood levels of, in monitoring of shock therapy, 7
Lag screws
fracture fixation technique using, 1000-1002, 1008f, 1011f
removal of, 1026
Lahy right-angled forceps, 141, 143f
Lameness
definition of, 894
evaluation of, 894-897
diagnostic anemia in, 901-902
applications of, 903
complications of, 903
emergency evaluation of, 902
intravascular
in forelimb, 909, 916-917f, 918f
in hindlimb, 909, 916-920f, 927f
local infiltrations for, 909, 914
perineural
in forelimb, 903, 904-908f, 909f
in hindlimb, 903, 906-913f, 914f
precautions for, 902-903
for stifle injuries, 1317
technical aspects of, 901-902
diagnostic imaging in, 922-945
of carpus, 917-938
clinical application of, 894-900.
Laminectomy
decompression, subtotal dorsal, 673-676, 675f
aftercare for, 676
indications for, 673-674, 675f
postoperative management of, 676
preoperative preparation for, 675
surgical positioning for, 674-675
surgical technique for, 675-676
Laminin
stress-induced, 998
surgical management of, 1213-1215, 1214f
Langerhans peritoneal elevators, 147, 148f
Laparoscopy
in colic evaluation, 391, 391f
ovariectomy using, 858
renal biopsy guided by, 872
in small intestinal obstruction diagnosis, 407-408
standing, diagnostic, technique for, 391-392, 392f
for surgery on bladder, 885
on ovaries, 856
on urinary tract, 867-868
on uterus, 856
Laparotomy
exploratory, septic peritonitis complicating, 508-509
ovariectomy using, 857-858, 858f
standing flank, for nephropleural entrapment in large colon, 456
for surgery on ovaries, 856
on uterus, 856
Large (ascending) colon, 446-465
impaction of, 448-452
sand, 451-452

Tunel grafts, 282-283, 282f

Tympanic, gullet pouch, 593, 594f

laser therapy for, 185

Typhlitis, partial, coccecal intussusception reduction through, 444
Wound(s) (Continued)
of extremities, management of, 301–302, 301f, 302f
of head and neck, management of, 299–300, 299f, 300
management of, 299–302, 299f, 300f, 301f, 302f
of thorax, management of, 300–301, 300f
management of, in emergency fracture treatment, 973
penetrating, 956, 957f
puncture, of foot, 1193–1195, 1194f, 1195f, 1196f, 1197f
repair of, 44–62. See also Wound repair
superficial
assessment of, 288
bacteria in, 292–293
closure of
for contaminated wound, 293
delayed primary, 294, 294f
options for, 292
primary, 293–294
by second-intention healing, 294–295
techniques of, 293–295, 294f
débridement of, 289–291, 290f, 291f, 292f
first aid for, 288
healing of
second-intention, 294–295
stages of, 292
management of, 288–298
corticosteroids in, 297
dressings in, 295–296, 295f, 296f, 297, 297f
growth factors in, 296–297
initial, 289, 289f
nonsteroidal anti-inflammatory drugs in, 297
tetanus prophylaxis for, 297
thoracic, 620–621
Wound repair
acute inflammation in, 45–47, 46f, 47f
cellular proliferation in, 47–49
elements influencing, 57–59
epithelialization in, 49–50
matrix synthesis and remodeling in, 50–53
mediators of, 53–57
phases of, 45–53, 45f
Wry nose, 1358–1359, 1361f
INDEX
X
X-ray production, 922–923, 922f
Xenograft(s), 269, 285
definition of, 1030
for skin graft donor site, 283
Xylazine
dosages of, during recovery, 240t
for epidural analgesia, 250t
infusion rate for, 89t
mode of action of, 247–248
for sedation of foal, 230
Y
Y-to-V-plasty, in reconstructive surgery, 263
Yankauer suction tip, 146, 146f
Yohimbine, for postoperative ileus, 504
Young’s modulus, of bone, 993
Z
Z-plasty, in reconstructive surgery, 263–264, 264f
Zimmer mechanical skin mesher, 277, 277f
Zinc, wound repair and, 58
